and helps reduce the flexion deformity that is typical for these fractures. Either a radiolucent triangle or bolster can be used (FIG 3H).

**Approach**

- Use fluoroscopy to determine which approach will allow the starting point to be placed just medial to the lateral tibial spine on the AP view and at the anterior articular margin on the lateral view.
- For diaphyseal and distal metaphyseal fractures, any of the following approaches is appropriate. As mentioned earlier, the patient’s anatomy can be used to determine which approach allows for appropriate starting point placement.
  - Medial parapatellar
  - Transpatellar tendon. (This approach may be avoided by some surgeons due to previous retrospective series that showed an increased likelihood of knee pain with this approach. However, other retrospective series and more recent prospective trials have found no association between knee pain and the surgical approach used.)
  - Lateral parapatellar
  - Proximal metaphyseal fractures
- The lateral parapatellar approach allows for guidewire and nail placement in the more lateral position, which is beneficial in countering the valgus deformity associated with these fractures. It also allows intramedullary nailing in the familiar hyperflexed knee position.

**FIG 3**

- A. The fractured leg is positioned in calcaneal skeletal traction on the fracture table. This provides excellent mechanical traction but limits limb mobility, especially knee flexion.
- B. The knee is flexed over a positioning triangle in preparation for the surgical approach.
- C, D. The tibial fracture is distracted and reduced using a mechanical distraction device with proximal and distal half-pins. (continued)
The semi-extended position allows for reduction of the flexion deformity associated with these fractures. The limited or formal medial parapatellar may be used if the surgeon is unfamiliar with the suprapatellar approach and special instrumentation is not available. If the suprapatellar approach is being performed, a superomedial or superior midline is used and special instrumentation is required. All of the surgical approaches are performed with the knee in the semi-extended position.

### SURGICAL APPROACH

#### Medial Parapatellar Tendon Approach

- Palpate and mark the medial border of the patellar tendon ([TECH FIG 1, line A]).
- Incise the skin at the medial border of the patellar tendon.
- Full-thickness skin flaps are developed.
- Dissection is carried down to the retinaculum.
- The retinaculum is then split, and the patellar tendon is retracted laterally.
- Do not incise the capsule.

#### Transpatellar Tendon Approach

- Palpate and mark the medial and lateral border of the patellar tendon, the inferior border of the patella, and the tibial tubercle ([TECH FIG 1, line B]).
- Incise the skin starting at the inferior margin of the patella and continue distally in the middle of the patellar tendon.
- Full-thickness skin flaps are developed.
- Incise the paratenon in the midline, and elevate medial and lateral flaps to identify the margins of the patellar tendon.
- Make a single full-thickness incision in the midline of the patellar tendon. Do not incise the capsule and avoid injuring the menisci at the inferior margin of the incision.

#### Lateral Parapatellar Tendon Approach

- Palpate and mark the lateral border of the patellar tendon ([TECH FIG 1, line C]).
- Incise the skin at the lateral border of the patellar tendon.
- Full-thickness skin flaps are developed.
- Dissection is carried down to the retinaculum.
- The retinaculum is then split, and the patellar tendon is retracted medially.
- Do not incise the capsule.
Semi-Extended Position\textsuperscript{28}

Medial Parapatellar Approach

\begin{itemize}
\item Either a standard midline or limited medial skin incision can be used (\textit{TECH FIG 2}).
\item Full-thickness skin flaps are developed.
\item The distal portion of the quadriceps tendon is incised, leaving a 2-mm cuff of tendon medially for later repair.
\item A formal medial arthrotomy is done extending around the patella, leaving a 2-mm cuff of capsule and retinaculum for later repair, and continuing along the medial border of the patellar tendon.
\end{itemize}

Suprapatellar Approach\textsuperscript{30}

\begin{itemize}
\item The suprapatellar approach requires special nail insertion instrumentation as well as cannulas for guide pin placement and reaming.
\item The skin incision is made at the superomedial edge of the patella (\textit{TECH FIG 3}).
\item Full-thickness skin flaps are developed.
\end{itemize}

\textit{TECH FIG 2} • \textbf{A.} A formal full medial parapatellar approach allows for easy patellar subluxation and start site localization but requires significant dissection. \textbf{B.} The alternative is a limited medial approach. (B: Courtesy of Paul Tornetta III, MD.)

\textit{TECH FIG 3} • A partial medial parapatellar arthrotomy that is carried into the intermedius allows enough subluxation of the patella to perform semi-extended nailing. (Courtesy of Paul Tornetta III, MD.)

\textbf{Standard Intramedullary Nailing}

\textbf{Initial Guidewire Placement}

\begin{itemize}
\item Drape the leg free, including the proximal thigh. Draping the leg more distally can limit knee flexion due to bunching of the drapes.
\item Flex the knee over a bolster or radiolucent triangle
\item A padded thigh tourniquet can be applied and inflated during the surgical approach, but it must not be inflated during reaming because of the risk of thermal injury to the intramedullary canal. For this reason, a thigh tourniquet is usually omitted.
\item The starting guidewire is placed on the skin and radiographically aligned with the anatomic axis and in line with the lateral tibial spine on a true AP fluoroscopic image. The skin can be marked along the guidewire path to allow visualization of the anatomic axis without fluoroscopy (\textit{TECH FIG 4A}).
\item The appropriate surgical approach is performed.
\item The knee is maximally flexed, and the guidewire is aligned with the anatomic axis of the tibia.
\item Typically, achieving an appropriate insertion vector will require the wire to be pushed against the patella or the peripatellar tissues.
\item The anterior tibial crest is palpated for frontal plane wire alignment.
\item Lateral plane fluoroscopy is necessary to place the wire at the proximal and superior aspect of the “flat spot” and near parallel with the anterior tibial cortical line (\textit{TECH FIG 4B}).
\item The guidewire is directed 8 to 10 cm into the metaphysis.
\end{itemize}
Creating and Reaming the Starting Hole

- The opening reamer (matching the proximal nail diameter) is introduced via a tissue sleeve and inserted while carefully maintaining knee hyperflexion and biplanar alignment.
- If the knee is allowed to extend or posterior pressure is not maintained on the tissue sleeve, the starting hole will become enlarged anteriorly, and the proximal anterior cortex will be violated.
- Imprecise reaming technique leads to anteriorization of the nail and violation of the proximal anterior cortex (TECH FIG 5).

Fracture Reduction

Simple Middle Diaphyseal Fractures (Transverse or Short Oblique)

- Manual traction with gross manipulation will reduce simple transverse mid-diaphyseal fractures.
- Medially-based external fixation or distraction with a large universal distractor is helpful for reduction when no assistants are available, in large patients, or when used for provisional fixation.
- Muscular paralysis often is helpful.
- Placement of percutaneous pointed reduction forceps can be helpful in oblique and short oblique patterns to achieve anatomic or near-anatomic reduction.
- Introduce a small or large pointed clamp under fluoroscopic guidance to determine the approximate clamp application angle (TECH FIG 6A–C).
- Typically, the spike on the distal fragment is posterolateral.

Highly Comminuted Middle Diaphyseal Fractures

- Have comparison radiographic images of the uninjured extremity available to be used as a template for length and rotational reduction landmarks.
Mechanical traction with medially based half pin fixation is very helpful.

- A large external fixator or large universal distractor is equally effective.
- The proximal half-pin is placed posteriorly and parallel to the tibial plateau (TECH FIG 7A).
- The distal half pin is placed just above and parallel to the plafond (TECH FIG 7B).
- The intramedullary reduction tool available in most nail or reamer sets can be used to manipulate the proximal fragment in order to advance the tool across the fracture which achieves fracture reduction and guidewire placement.

Open Middle Diaphyseal Fractures

- Large segmental and butterfly fragments that are completely devitalized and void of soft tissue attachments should be removed and cleaned of contamination.
- These pieces can then be reintroduced into the fracture site and used to perform anatomic open reduction following passage of the intramedullary rod and interlocking. These pieces should be removed after fixation is completed because they represent a large amount of nonviable material in a high-risk wound.
- Occasionally, an osteotome is required to free near-circumferential fragments (TECH FIG 8A–C).
- If reduction is difficult, a small-fragment unicortical plate can be used to maintain the reduction during reaming and nail placement. Once interlocking is completed, the plate should be removed (TECH FIG 8D).

Passing the Guidewire

- Once optimal AP and lateral plane reduction is achieved, the wire is advanced past the level of the fracture. Verify that the wire is within the canal on both the AP and lateral views to avoid advancing too far and damaging extramedullary structures.
- In metadiaphyseal fractures, the wire must be centered in the metaphyseal segment.
- In proximal and distal fractures, blocking screws or half-pins may be required to ensure centralized positioning of the guidewire (TECH FIG 9A,C,D).
- Once centralized, the ball-tipped wire must be impacted into the subchondral bone of the tibial plafond at the
level of the physeal scar. This decreases the risk of inadvertently removing the guidewire during reaming.

- Nail length measurement can now be performed using supplied length gauges, and should be verified with lateral fluoroscopic measurement (TECH FIG 9B). The lateral view is used because it is more accurate in determining the level of the articular surface and avoiding nail prominence.

- Alternatively, inserting a guidewire of the same length to the nail entry site and then measuring the length differential between wires also provides an accurate measurement (TECH FIG 9C). However, this introduces the significant cost of a second guidewire.

- Device manufacturers supply nails in variable increments. When a length measurement falls in between lengths, choose the shorter length. A threaded end cap (usually 5, 10, and 15 mm) can be used if it is desired to bring the nail to top of the canal opening.

- Leaving the nail countersunk below the bone surface does not compromise stability in middle and distal fractures, but may complicate future nail extraction.

### Reaming the Canal

- Before reaming, estimate the narrowest canal diameter using both AP and lateral plain radiographs. Alternatively, intramedullary reamer sets typically have a radiolucent ruler that allows for intraoperative fluoroscopic verification, which should be done on both the AP and lateral views. The canal typically is reamed at least 1 mm over the isthmic diameter to minimize the risk of nail incarceration.

- Reaming should begin with an end-cutting reamer—the 8.5- or 9-mm size in most systems.

- Reamer heads should be evaluated before insertion and should be sharp and free of defects.

- Insert the reamer head into the proximal metaphysis with the knee in maximal flexion before applying power to avoid distorting the entrance hole (TECH FIG 10A).

- Reamers are advanced at a slow pace under full power.

- If the reamer shafts are not solid, but are wound, be sure to avoid using reverse when drilling, because that would cause the reamers to unwind if resistance is encountered within the IM canal.
Care must be taken not to inadvertently extract the guidewire when the reamers are removed.

Multiple techniques are utilized. First, manual downward pressure can be applied to the wire with specialized instruments, medicine cups, or cleaning cannulas (TECH FIG 10B).

Once the reamer has cleared the opening, it can be clamped and held in position (TECH FIG 10C).

For the minimally reamed technique, a single end-cutting reamer (usually 9 mm) is passed down the canal to ensure the smallest diameter nail can pass through the narrowest segment of the intramedullary canal.

In an effort to minimize thermal damage to the endosteal cortex, reaming should be discontinued within 0.5 to 1 mm of hearing the reamer head catching (“chatter”) on the endosteal cortex.

Care also should be used when there are butterfly or oblique fracture fragments. Continued reaming after encountering “chatter” may result in iatrogenic comminution and loss of reduction.

Unreamed Technique

Standard preparation technique is used for the starting hole, and the fracture is reduced.

Precise evaluation of the lateral isthmic diameter is repeated, and a small-diameter nail is selected, typically in the 7- to 9-mm range.

A good guideline is to use a nail 1 mm to 1.5 mm smaller than the narrowest measure of the isthmus on the lateral radiograph.

If lateral plane imaging is suggestive of canal diameter very close to nail size, a single pass with an end cutting reamer usually is performed to decrease the possibility of nail incarceration.

The nail is inserted and impacted in standard fashion. If significant resistance is encountered when the nail reaches the isthmus, the nail is removed to avoid incarceration or iatrogenic fracture propagation. A reamer 0.5 to 1.0 mm larger than the nail is passed down the canal, and nail passage is attempted again.

Nail Insertion

After the nail insertion handle is attached, pass a drill through the proximal screw insertion attachment and screw insertion cannulas before inserting the nail to ensure accurate alignment of the attachment.

Maintain nail rotation during insertion by aligning the center of the insertion handle with the tibial crest; consider internal rotation of the nail if distal anteroposterior interlocking bolts are deemed necessary.

Maintain knee hyperflexion during nail insertion to minimize the risk of posterior cortical abutment and iatrogenic fracture.

Impact the nail to the final depth using lateral plane fluoroscopy.

Interlocking Bolt Insertion

In simple transverse fractures, place distal interlocks first to allow for back-slapping for interfragmentary compression and gap minimization.

Usually, distal interlock bolts are placed medial to lateral.

Position the leg in slight extension and stable neutral rotation.

Rotate the C-arm to lateral imaging position and pull the tube back away from the medial side of the leg to allow for drill placement.
Rotate the leg and C-arm individually and sequentially to create a perfect circle image; optimize this view before drilling attempts (TECH FIG 11A).

After localizing the interlocking hole using a clamp and fluoroscopy, make an incision large enough to place the locking bolt. Use blunt clamp dissection until the cortex is reached.

Use a sharp drill point and place the center of the point in the center of the circle

Hold the drill obliquely to the nail axis to simplify repositioning (TECH FIG 11B).

Once the central location is achieved; align hand and drill with imaging axis.

Fluoroscopes with laser alignment guides can be helpful to assist with alignment by centering the laser on the skin incision and then placing the laser in the center of the back of the drill when preparing to drill the hole (TECH FIG 11C).

Drill to the mid-sagittal point in the tibia. Then disengage the drill from the drill bit and check the fluoroscopic image.

If the drill is accurately positioned in the center of the hole, advance the drill bit with power through the far cortex; avoid broaching the far cortex by impacting with a mallet to avoid iatrogenic fracture.

Drill the second interlock hole using the same technique but maintaining a parallel axis with the first successful drill passage.

Replace the drill with the appropriate depth gauge and check an AP image before screw length selection.

Once interlock lengths and position are verified, “back slapping” can occur to optimize compression.

Using the slotted mallet attachment on the insertion handle, superiorly directed mallet blows can be used while pressure is applied to the foot in order to compress the fracture site. Fluoroscopy should be used to monitor the amount of compression and the nail position proximally. If “back slapping” is planned, the nail should be slightly overinserted to avoid nail prominence after compression is performed.

Place proximal interlocks through drill guides.

Because the tibia is a triangle, oblique views may be used to more accurately judge screw length for transverse locking bolt measurement.

If oblique locking bolts are chosen proximally, oblique fluoroscopic views should be used prior to insertion handle removal to avoid placing long screws that are particularly symptomatic on the medial side of the knee and to avoid injury to the peroneal nerve posterolaterally.

PROXIMAL METAPHYSEAL TIBIA FRACTURES

As described in the anatomy section, proximal metaphyseal tibia fractures have a tendency to be displaced in valgus and flexion. Malunion occurs in up to 84% of proximal tibia fractures that undergo intramedullary nailing.

In addition to the technical tricks that we will discuss, nail design can be important in avoiding malunion. Nails with a more proximal bend are less likely to cause displacement of the fracture. Nail designs with oblique proximal locking bolt options have been shown to provide more biomechanical stability than designs with transverse locking bolts alone.

Several current nailing systems allow a fixed angle to be created between the nail and the proximal locking bolt by inserting an end cap that creates an interference fit with the proximal locking bolt, and others have mechanisms to allow the screw to lock into the nail.

Use of a variety of the techniques described in the following sections below often is required to achieve and maintain frontal and sagittal plane reduction. The most important element is the proper starting site and guidewire insertion vector. Posteriorly directed insertion angles will accentuate proximal fragment extension with nail
passage regardless of nail design. Medial deviation of the guidewire will lead to abutment against the steep medial cortex and lead to valgus angulation at the fracture site with nail insertion.

**Lateral Parapatellar Tendon Approach**
- After completing the lateral parapatellar approach described, the standard patient positioning is used.
- The lateral parapatellar approach allows the guide pin to be more easily placed just medial to the lateral tibial spine on the AP view and along the lateral cortex to correct the valgus angulation.
  - If a true AP view is not obtained and the leg is externally rotated, the starting point will be more medial than desired.\(^5\)
  - It is important to get enough knee flexion over the radiolucent triangle or bolster to allow for the guide pin to be placed as proximal as possible and parallel along the anterior tibial cortex to help correct the typical flexion deformity.\(^22\)

**Semi-extended Technique**
- The benefit of the semi-extended technique for proximal metadiaphyseal fractures is that the leg position helps neutralize the associated flexion deformity.\(^28\)
- The patient is placed in the semi-extended position as described earlier.
- The open medial parapatellar approach can be used (see TECH FIG 1, line C).
  - Using the previously described surgical approach, the patella is subluxated to allow for guide pin placement, reaming, and nail placement, with the knee remaining in the semi-extended position.
  - No special instruments are required.
- Suprapatellar approach\(^30\)
  - Either the superomedial or direct superior approach is used.
  - Special instrumentation is required; which instrumentation is needed depends on the specific system used.

**Adjunct Reduction and Fixation Techniques**

**Blocking/Pöller Screws**
- Screws can be placed across the intramedullary canal to create a “false” cortex in the metaphyseal area that narrows the potential space for the nail. This aids in both fracture reduction as the nail is being placed and maintenance of the reduction once the nail is seated.\(^15,26\)
- Locking bolts found in the nailing set or screws made from the same metal as the nail should be used.
- Blocking screws can either be placed prior to initial nail insertion or, if the nail is inserted and residual deformity exists, the nail can be removed and blocking screws can be inserted.
- Coronal and sagittal plane correction can be performed by placing a screw at the concavity of the deformity.
To correct valgus, the screw is placed laterally (TECH FIG 13A). To correct lateral plane extension, the screw is placed posteriorly (TECH FIG 13B).

The appropriately sized drill bit is placed with fluoroscopic assistance.

The appropriately sized screw replaces the drill bit.

The guidewire is then inserted and seated distally.

Intramedullary reaming is necessary to ensure the nail follows the newly created path.

When a screw that blocks the way is encountered, simply push the reamer head past the screw without reaming. This avoids dulling the reamer head and potentially displacing the blocking screw.

Once passed the screw, resume reaming.

After reaming is complete, insert the intramedullary nail.

If the displacement has not been corrected, it will be necessary to remove the nail, and additional screws may be added. Reaming and reinsertion of the guide-wire are required before re-inserting the nail.

Interlocking bolts through the nail are placed in the standard fashion (TECH FIG 13B,C).

Medial Unicortical Plate

If the metaphyseal fracture can be reduced but easily displaces with changes in position of the extremity, a medial unicortical plate can be used.

A medial or posteromedial (more proximally) skin incision is centered at the fracture site.

Full-thickness skin flaps are developed. If the pes anserinus tendons are encountered, they can be elevated anteriorly.

After the fracture is reduced in the coronal and sagittal planes, a plate of the appropriate length plate (either 3.5 mm compression plate, pelvic reconstruction, or one-third tubular) is applied more posteriorly and fixed with two or three unicortical screws on either side of the fracture that are long enough to maintain the reduction, but avoid impeding the passage of the intramedullary reamers and nail (TECH FIG 14).

Ipsilateral Tibial Plateau Fracture

Lag Screw Fixation for Simple Fractures

Reduce and compress the articular surface with periarticular reduction forceps through small incisions medially and laterally.

Provisionally fix the articular fracture with at least two K-wires or cannulated screw guidewires that are parallel to the articular surface.
Either cannulated or solid core screws can be used for lag screw fixation (TECH FIG 15).

If there is comminution, avoid over-compressing the articular surface.

Avoid placing screws anteriorly where the nail will be inserted.

Lateral Tibial Plateau Plate

Reduce and provisionally fix the tibial plateau component as described in Chapters TR-13 and TR-14.

Because of the difficulty of placing bicortical screws in the metaphyseal and diaphyseal areas without impeding nail insertion, a locking plate should be considered, since unicortical locking screws are available distally (TECH FIG 16).

Oblique fracture patterns, which often are encountered, are amenable to percutaneous clamp reduction (TECH FIG 17A).

Half-pin joysticks are helpful for manipulating and reducing the distal fracture segment (see Fig 3E).

With a fibula fracture near the level of the tibial fracture, fibular fixation can be helpful in achieving reduction (TECH FIG 17B). The soft tissues must be tolerant of a lateral or posterolateral approach to fibula, however.

Simple transverse fractures can be fixed with intramedullary technique using flexible titanium nails, typically 2.5 mm in diameter, or 3.5 mm intramedullary screw fixation.

Plate fixation along the lateral or posterolateral surface is used most often.

Anatomic restoration of length and rotation is critical for accurate restoration of tibial length, especially with comminuted tibial fracture patterns or when tibial bone loss is present.

Medially-based external fixation or universal distractor placement with half-pin placement just above the articular surface of the ankle joint or with fixation into the medial calcaneus often is helpful to aid in the reduction of the tibia fracture, even in the presence of stable fibular fixation.
Chapter 16  INTRAMEDULLARY NAILING OF THE TIBIA 657

TECH FIG 17 • A. Distal oblique fractures can be effectively reduced with percutaneous clamp application. B. Anatomic fibular reduction often can align a tibial fracture in near-anatomic position.

PEARLS AND PITFALLS

| Starting point | The starting point should be at the anterior articular margin and just medial to the lateral tibial spine. Starting too medial and distal for proximal metaphyseal fractures results in a valgus and flexed malunion. |
| Centering the guidewire | Center the guidewire distally on the AP and lateral views. If not centered, the nail will follow the path of the reamer and guidewire, which will malreduce the fracture. |
| Measuring nail length | Measure on the lateral view. Measuring on the AP view will potentially lead to a nail that is too long, with articular prominence causing knee pain or articular surface damage. |
| Femoral distractor or external fixator for reduction | Half-pins can be placed outside of the path of the nail. The best positions are posterior in the proximal tibia and distally very close to the subchondral bone of the tibial plafond. Placement of the proximal pin too anteriorly and the distal pin too proximally may impede reaming and nail insertion. |
| Unicortical plates for reduction | Metadiaphyseal plates contribute to stability and maintenance of reduction, and removal can lead to loss of reduction after nail passage. Diaphyseal reduction plates; however, should be removed to prevent rigid fixation of the fracture gap. |
| Blocking screws/Pöller screws | Use interlocking bolts from nail instrumentation rather than small fragment screws to avoid screw breakage during nail passage. Do not remove screws, because they provide stability and help maintain reduction. Use caution when using a drill bit because it is prone to breakage during nail insertion, and removal after nail passage may destabilize the construct. |
| Posterior malleolus | Critically evaluate the posterior malleolus in distal diaphyseal and metaphyseal fractures pre-, intra-, and postoperatively. If a posterior malleolar fracture or articular involvement is missed, ankle subluxation or displacement of the articular surface can occur with weight bearing. |

POSTOPERATIVE CARE

- Weight bearing as tolerated, unless there is articular involvement
- Posterior splint or cam walker
- Early range of motion
- Suture removal at 2 to 3 weeks postoperatively
- Strengthening after at 6-week clinic visit
  - Consider a quadriceps-specific program.
- After the 6-week visit, return clinic visits are made at 6- to 8-week intervals until the bone is clinically and radiographically healed.

OUTCOMES

- Long-term follow-up of patients treated nonoperatively reveals persistent functional deficits and dysfunction, including stiffness, pain, and loss of muscle power.\(^8,17,24,25\)
- Anterior knee pain is common (50% to 60%), and patients should be informed of this preoperatively.\(^7,13\)
- This knee pain is more common in young patients. It typically is mild and may be exacerbated by kneeling, squatting, or running
- Its occurrence is not dependent on surgical approach.
- Nail removal leads to pain resolution in about one half of patients and decreased pain in another one fourth.\(^7\)
- At late follow-up after tibial nailing, patients’ function is comparable to population norms, but objective and subjective evaluation shows persistent sequelae, including knee pain, persistent swelling, muscle weakness, and arthritis—many of which are not insignificant.
- Malunion has an unclear association with development of arthritis.
- Some authors have associated even mild deformity with increased risk of osteoarthritis.\(^14,34\)
COMPLICATIONS\textsuperscript{5,27}

Infection
- Closed fractures: about 1%
- Open fractures
  - Type I: 5%
  - Type II: 10%
  - Type III: over 15%
- Condition of the soft tissues is key for risk of infection and for outcome.

Nonunion
- Closed fractures: 3%
- Open fractures: about 1%, and may be higher, depending on the soft tissue injury
- Risk factors
  - Unreamed smaller-diameter nails with smaller locking bolts are associated with delayed or nonunion and an increased risk of locking bolt breakage.
  - Closed fractures carry a risk of severe soft tissue injury, eg, internal degloving.
- Open fractures may be accompanied by severe soft tissue injury.
  - Delayed bone grafting may be warranted for treatment of bone loss.
  - The use of RhBMP-2 is FDA-approved in open tibia fractures.\textsuperscript{9} It decreases the nonunion rate by 29%, and decreased secondary interventions. BMP-2 combined with allograft for delayed bone grafting procedures in tibia fractures with cortical defects have shown a similar rate of healing to autograft with the benefit of decreased donor site morbidity.\textsuperscript{12}
- Compartment syndrome
- Fracture pattern—transverse
- Host factors
  - Tobacco use
  - Medications: bisphosphonates, nonsteroidal anti-inflammatory drugs
  - Diabetes mellitus
  - Vascular disease
  - Malnutrition—albumin level lower than 34 g/L and a lymphocyte count below 1500/mm\textsuperscript{3}
- Infection

Malunion
- Occurs in up to 37% of all tibial nailing procedures
- Malunion is seen in as many as 84% of patients with proximal metaphyseal tibia fractures.
- These can be avoided with proper surgical techniques.

REFERENCES

Compartment syndrome remains one of the most devastating orthopedic conditions. The potential clinical sequelae and medicolegal implications of a possible missed compartment syndrome make it one of the most important entities in all of orthopedic surgery. 

Compartment syndrome is a condition, with numerous causes, in which the pressure within the osteofascial compartment rises to a level that exceeds intramuscular arteriolar pressure, resulting in decreased blood flow to the capillaries, decreased oxygen diffusion to the tissue, and ultimately cell death. This is a true orthopaedic emergency.

The clinical sequelae of a missed compartment syndrome can be life- and limb-threatening. Myonecrosis can lead to acute renal failure and multiorgan failure if not appropriately managed.20

Richard von Volkmann first documented nerve injury and subsequent contracture from compartment syndrome in 1872 following a supracondylar fracture.

In 1906, Dr. Hildebrand was the first to apply the term “Volkmann ischemic contracture” to define the end result of any untreated compartment syndrome.

In 1909, Dr. Thomas described the major causes of compartment syndrome (fractures being the predominant cause) after reviewing the 112 cases published up to that date.

The first to suggest that fasciotomy may help prevent contracture was Dr. Murphy in 1914.

It was not until 1967 that Seddon, Kelly, and Whitesides described the existence of four compartments in the lower leg and the need to decompress more than just the anterior compartment.

Any situation that leads to an increased pressure within the compartment may result in a compartment syndrome.

The impermeable fascia prevents fluid from leaking out of the compartment and also prevents an increase in volume that could reduce pressure within the compartment.

The incidence of compartment syndrome is 7.3 per 100,000 males and 0.7 per 100,000 females.

In those cases, the most common cause was fracture followed by soft tissue injury.

McQueen et al found that the incidence of compartment syndrome was nearly equal for both high- and low-energy injuries and that open wounds did not decompress the compartments and were not protective.13,14

This chapter describes acute compartment syndrome, in contrast to exertional compartment syndrome.

Exertional compartment syndrome is a transient chronic condition brought on by exercise. Unlike acute compartment syndrome, exertional compartment syndrome is not an emergency and its treatment is beyond the scope of this chapter.

The lower leg has four compartments: the anterior, lateral, superficial posterior, and deep posterior (FIG 1, Table 1).

The anterior compartment is bound anteriorly by fascia, laterally by the anterior intermuscular septum, and posteriorly by the intersosseous membrane between the fibula and tibia.

The four muscles in this compartment are the tibialis anterior, extensor digitorum longus, extensor hallucis longus, and peroneus tertius.

The neurovascular bundle includes the deep peroneal nerve and the anterior tibial artery.

The deep peroneal nerve provides sensation to the first dorsal web space of the foot and motor function to all the muscles in the anterior compartment.

The anterior tibial artery travels in this compartment just anterior to the tibiofibular intersosseous membrane and continues in the foot as the dorsalis pedis artery.

The lateral compartment is bordered anteriorly by the fascia, posteriorly by the posterior intermuscular septum, and medially by the fibula.

There are only two muscles of the lateral compartment: the peroneus longus and the peroneus brevis.

The major nerve supply to the lateral compartment is the superficial peroneal nerve, which supplies the two muscles of the compartment. The nerve supplies sensation to the dorsum of the foot, except the first dorsal web space.

Since the deep peroneal nerve courses proximally around the fibular head, both the deep and superficial peroneal nerves travel within this compartment.

There are no main vessels in this compartment, and the muscles receive their blood supply from the peroneal and posterior tibial arteries.

The deep posterior compartment contains the flexor digitorum longus, tibialis posterior, and flexor hallucis longus muscles.

Although it is not considered a separate compartment, the tibialis posterior muscle can have its own fascial covering.

The deep posterior compartment contains the main neurovascular bundle of the posterior compartment, which consists of the tibial nerve, posterior tibial artery and vein, and peroneal artery and vein.

The superficial posterior compartment contains the gastrocnemius, soleus, and plantaris muscles, which are supplied by branches of the tibial nerve, posterior tibial artery, and peroneal arteries.

There is no major artery that travels in this compartment.

**PATHOGENESIS**

Although the exact pathophysiology is not completely understood, the premise of the syndrome is either a decrease in the space available for the tissues within the fixed compartment or an increase in the size of the tissues within the compartment.
Either case can result in an increase in pressure above a critical value.

- Increased fluid content and swelling of damaged muscles can be caused by the following:
  - Bleeding into the compartment (from fractures, large vessel injury, or bleeding disorders)
  - Fractures are the most common cause of compartment syndrome. It is estimated that 9.1% of tibial plateau fractures develop compartment syndrome.3
  - Blunt trauma is the second most common cause, accounting for 23% of cases.14
  - Increased capillary permeability (e.g., burns, ischemia, exercise, snake bite, drug injection, intravenous fluids)
  - Decreased compartment size can be caused by the following:
    - Burns
    - Tight circumferential wrapping, dressings, casts
    - Localized external pressure, such as lying on the limb for an extended period of time or from pressure on the “well leg” in the lithotomy position on the fracture table
  - Elevated pressure prevents perfusion of the tissue from the capillaries and results in anoxia and necrosis.
  - The impermeable fascia prevents fluid from escaping, causing a rise in compartment pressure such that it exceeds the pressure within the veins, resulting in their collapse or an increase in the venous pressure.17
  - The final event is cellular anoxia and necrosis.20
  - During necrosis there is an increase in the intracellular calcium concentration coupled with a subsequent shift of water into the tissue, causing the tissue to swell further, adding to the pressure.4 This “capillary leakage” adds to the increased pressure in the compartment, thus creating a vicious cycle.
  - The effects on muscle and nerve function are time-dependent.
  - Prolonged delay results in greater loss of function.
  - After sustained elevation of compartment pressures greater than 6 to 8 hours, nerve conduction is blocked.10 In an animal study, irreversible muscle damage occurred after 8 hours.22
  - The exact pressure at which change within the compartment occurs has been subject to debate and has evolved over time.
    - Initially, the pressure of 30 mm Hg was reported to be the maximum pressure above which irreversible muscle damage occurred.27
    - Currently, clinicians have recognized the importance of the patient’s blood pressure when considering the compartment pressure and use an absolute difference between diastolic blood pressure and compartment pressure of 30 mm Hg as a gauge.
Animal studies have highlighted the importance of the systemic pressures relative to the compartment pressure.

- Heckman et al found that irreversible ischemic changes occurred when the compartment pressure was elevated within 30 mm Hg of the mean arterial pressure and within 20 mm Hg of the diastolic pressure.²⁷
- Studies on limb ischemia at the University of Pennsylvania had similar conclusions.
  - They coined the term “delta P” referring to the difference between the mean arterial pressure minus the compartment pressure, with a lower number reflecting less blood flow.¹
  - They found that cellular anoxia and death occur with pressure within 20 mm Hg of the mean arterial pressure; however, at pressures within 40 mm Hg there was reduced oxygen tension but no evidence of anoxia, and aerobic metabolism persisted.
- McQueen and Court-Brown used the cutoff of compartment pressure within 30 mm Hg of the diastolic blood pressure as a fasciotomy threshold.¹⁵
  - There were no adverse clinical outcomes from not releasing compartments with pressures more than 30 mm Hg from the diastolic blood pressure, and this has come to be the value currently used most often as a threshold for compartment syndrome.

### Natural History

- The outcome of compartment syndrome depends on location and time to intervention.
  - Six hours of ischemia is currently the accepted upper limit of viability. Rozarbeck and Macnab reported almost complete recovery of the limb function if fasciotomies are performed within 6 hours of the onset of symptoms.²¹
  - Muscle undergoes irreversible change after 8 hours of ischemia, whereas nerves can have irreversible damage after as short as 6 hours.¹⁰
  - Compartment syndrome may have broad effects on multiple systems.
    - As muscle necrosis occurs, myoglobin, potassium, and other metabolites are released into circulation.
    - As a result, several metabolic conditions can arise, including myoglobinuria, hypothermia, metabolic acidosis, and hyperkalemia. In turn, these biochemical phenomena can cause renal failure, cardiac arrhythmias, and potentially death.

### Patient History and Physical Findings

- The use of physical examination findings to diagnose compartment syndrome has not been well validated.²⁶ However, physical examination findings are widely used in clinical practice.
- The key to successful handling of compartment syndrome is early diagnosis and treatment. Therefore, the orthopedic surgeon must be familiar with the signs and symptoms of the diagnosis and perform a detailed documented history and physical.
- The patient’s history is critical. Certain aspects of the patient’s history may make the syndrome more likely.
  - The existence of any of the following characteristics should heighten the surgeon’s suspicion: high-energy mechanism, a patient on anticoagulation, or a patient with a tight circumferential dressing.
- A patient will often not demonstrate all of the classic “six Ps”: pain, paresthesias, pulselessness, pallor, paralysis, and pressure.
  - Pulselessness has recently been regarded as less of an indicator; patients can suffer extensive compartment syndrome with normal pulses.
  - Likewise, pallor reflects loss of arterial flow and is rarely present on physical examination.
  - Perhaps the most sensitive and earliest sign of compartment syndrome is pain with passive stretch of the muscles of the compartment.⁴
  - Pain out of proportion to the injury is also an early symptom of the diagnosis.
  - Pain may be absent if compartment syndrome is already established and nerve injury has occurred.
  - Since small fiber nerves are affected first, light touch will be affected before pressure and proprioception.
  - The ability to use pain as an indicator may be diminished in patients unable to sense pain or communicate with the caregivers; in this situation the surgeon must use other means to make the diagnosis.
  - Patients in whom pain may be difficult to ascertain include those with head injuries, those using ethanol or drugs, those who are intubated or sedated, those who have major distracting injuries such as a long bone fracture, those receiving large amounts of pain medicine, or any other factor that might alter the patient’s ability to accurately sense and communicate pain levels.
  - Pain perception may also be altered due to anesthesia, and some reports suggest that patients receiving epidural anesthesia are four times more likely to develop compartment syndrome than those receiving other forms of pain control.¹⁹
  - This type of anesthesia results in a sympathetic nerve blockade, thereby increasing the blood flow, compounding the local tissue pressures and extremity swelling.
  - Similarly, local anesthesia combined with narcotics has been shown to increase the risk of compartment syndrome.⁵,¹⁹,²⁰
  - Paresthesia can be a useful, but confusing, symptom of compartment syndrome.
    - It has been shown, however, that nerve function is altered after only 2 hours of ischemia; therefore, it represents a potentially early symptom.⁸
    - With increased pressure in a compartment, the sensory nerves will be affected first, followed by the motor nerves (e.g., in the anterior compartment, the deep peroneal nerve is affected quickly, and patients will report loss of sensation between the first two toes).
  - Paralysis is often less useful since it may be caused by ischemia, guarding, pain, or a combination of these factors, particularly in patients with a distracting extremity injury such as a tibial shaft fracture.
  - Serial examinations are critical. All complaints should be investigated thoroughly, and all findings should be carefully documented in the chart such that subsequent examiners can refer to the record as a tool for diagnosis (see Exam Table for Pelvis and Lower Extremity Trauma, page 1).
- Measurement of the compartment pressure
  - Stryker pressure monitor is most common (FIG 2).
  - Arterial line (16- to 18-gauge needle) is easy to do in the operating room, but the pressure measured with a simple needle is thought to be 5 to 19 mm Hg higher than the pressure measured with a side port or wick catheter.¹⁶
  - Pressure values should be recorded for all four compartments. Typically each compartment is checked twice. If there
that either the flexor or extensor hallucis longus is firing. “NVI” is also not useful as it does not state the exact muscle groups that were tested.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- The diagnosis of compartment syndrome is typically made clinically. There are, however, adjunct investigations that can be used to confirm or rule out the diagnosis.
- Once a patient is diagnosed with compartment syndrome, fasciotomies should be performed emergently. Any workup that could delay this process should be undertaken with great caution.
- If the patient cannot provide clinical clues because he or she is sedated or for other reasons, or if the diagnosis is in question, compartment pressures can be measured.
- Several techniques to measure compartment pressures have been described, including the Whiteside infusion technique, the Stic technique, the Wick catheter technique, and the slit catheter technique. The two most commonly used techniques are the Whiteside side port needle and the slit catheter device.
- There are numerous commercially available digital pressure monitors that are frequently used as well.
- The exact pressure that defines compartment syndrome is still debatable, although a measured pressure should be taken with reference to the diastolic blood pressure.13
McQueen et al did a prospective study on 116 tibial shaft fractures that were monitored continuously for 24 hours. They set the criterion for compartment release at a difference between diastolic and compartment pressures of less than 30 mm Hg. Following this criterion, a total of three had fasciotomies and none of the sample had late sequelae of compartment syndrome 9 months later.

The indications to measure compartment pressures include the following: one or more signs or symptoms of compartment syndrome and a confounding factor (eg, local anesthesia), unreliable examination with firmness in an injured extremity, prolonged hypotension and a swollen extremity with firmness, and spontaneous increase in pain after having received adequate analgesia.

The technique of measuring compartment pressures must be mastered by the surgeon.

Inexperience with the technique may lead to inaccurate data and potentially missed compartment syndrome.

When measuring the pressure, the surgeon must be familiar with the local anatomy and able to accurately measure all of the compartments.

Location of the measurement is important.

Heckman et al reported the highest pressures were within 5 cm of the fracture site; pressures decreased as the measurements were taken distally and proximally to the fracture. They recommended that pressures be measured close to and both distal and proximal to the fracture in all compartments. The highest measurement is compared to the diastolic blood pressure and interpreted accordingly.

Lab studies should include a complete metabolic profile, a complete blood count with differential, creatine phosphokinase, urine myoglobin, serum myoglobin, urinalysis (which may be positive for blood but negative for red blood cells, indicating myoglobin in the urine due to rhabdomyolysis), and a coagulation profile (prothrombin time, partial thromboplastin time, INR).

Obtaining a complete laboratory panel should not delay operative treatment in a diagnosed case of compartment syndrome.

DIFFERENTIAL DIAGNOSIS

Compartment syndrome is diagnosed in a patient with either:

- Suspicious clinical findings as discussed above, or
- Pressure in a compartment within 30 mm Hg of the diastolic blood pressure

Other diagnoses to consider:

- Normal pain response secondary to fracture or other trauma
- Low pain tolerance secondary to preoperative substance abuse
- Muscle rupture
- Deep venous thrombosis and thrombophlebitis
- Cellulitis
- Coelenterate and jellyfish envenomations
- Necrotizing fasciitis
- Peripheral vascular injury
- Peripheral nerve injury
- Rhabdomyolysis

Of special note, in the case of envenomations, recent studies have shown that compartment syndrome is multifactorial and that fasciotomy may not prevent myonecrosis, which may be due to the direct toxic effect of the venom and the inflammatory response.

In these cases, antivenom should be administered; this has been shown to decrease limb hypoperfusion.

NONOPERATIVE MANAGEMENT

- All patients suspected of having acute compartment syndrome should have emergent fasciotomies performed in the operating room or at the bedside.
- “Nonoperative” treatment of acute compartment syndrome is never appropriate, as this is a life- and limb-threatening injury whose successful treatment is based on limiting the time until fasciotomy is performed.
- Nonoperative treatment of compartment syndrome is reserved for patients presenting very late after a missed compartment syndrome who already have irreversible muscle necrosis.
- One school of thought is that these patients should not be debrided, as it will only increase the chance of infection.
- This is controversial and applies only to chronic, missed compartment syndrome.
- There is consensus that all acute compartment syndromes should be treated operatively with fasciotomies.
- Since ischemic injury is the basis for compartment syndrome, additional oxygen should be administered to the patient diagnosed with compartment syndrome because it will increase slightly the blood partial pressure of oxygen (PO2).
- The surgeon must ensure that the patient is normotensive, as hypotension reduces perfusion pressure and leads to further tissue injury.
- Any circumferential bandages or casts should be removed in patients at risk for development of compartment syndrome.
- Compartment pressure falls by 30% when a cast is split on one side and by 65% when a cast is spread after splitting; splitting the padding reduces the pressure by an additional 10%, complete removal of the cast by another 15%. There could be a total of 85% to 90% reduction in pressure by just taking off the cast.
- Elevating the limb above the heart decreases limb mean arterial pressure without changing the intracompartmental pressure. The affected extremity should not be elevated.
- As shown by Styf and Wiger, after an elevation of 35 cm, the mean perfusion pressure decreased by 23 mm Hg but the intracompartmental pressure stayed the same.
- Intravenous fluids should be given to decrease the chance of kidney damage from myoglobin.
- The “crush syndrome” is a sequela of muscle necrosis (ie, high creatine phosphokinase level, above 20,000 IU) and manifests as nonoliguric renal failure, myoglobinuria, oliguria, shock, acidosis, hyperkalemia, and cardiac arrhythmias.
- Treatment is supportive, with ventilatory support, hydration, correction of acidosis, and dialysis.
- It is important in this situation to decrease the metabolic load by preventing ongoing tissue necrosis and debriding all dead tissue.
- The use of narcotics should be closely recorded and monitored in any patient suspected of having compartment syndrome.
- The use of local, spinal, or epidural anesthesia for postoperative pain control is generally discouraged in patients at high risk for compartment syndrome as it limits the ability of the clinician to do serial examinations.
SURGICAL MANAGEMENT

- All patients with acute compartment syndrome should be treated with emergent fasciotomies of the affected compartments, as compartment syndrome is limb-threatening as well as potentially life-threatening if allowed to progress to myonecrosis and renal failure.
- Time to diagnosis and surgical treatment of compartment syndrome is critical, as nerve damage after 6 hours of ischemia may be irreversible.
- Patients with compartment syndrome should be given the highest priority and treated as an operative emergency.
- Fasciotomy of the involved compartment is the standard of care for compartment syndrome.
  - In a trauma setting, typically all four compartments of the leg are released, regardless of evidence of involvement of the other compartments.
  - Fasciotomies should ideally be performed in the operating room.
  - If the patient is too ill to be transported to the operating room or there is no operating room available, fasciotomies can be performed at the bedside in as sterile an environment as possible.
  - The only contraindication to fasciotomy in the face of a compartment syndrome is delayed presentation, in which a patient with missed compartment syndrome presents more than 24 to 48 hours after irreversible injury has set in.
- Operative treatment is hypothesized to increase infection.
- It is often difficult to know when a compartment syndrome occurred, however, so in situations in which it is unclear, it is probably wise to release the compartments.
- One school of thought is that if the compartment syndrome has run its course, fasciotomies should not be performed unless the pressure in the compartment is within 30 mm Hg of diastolic pressure.
- Fasciotomies are also often performed in a prophylactic manner for any patient with an ischemic limb for more than 6 hours to prevent reperfusion injury.

Preoperative Planning

- Once compartment syndrome is diagnosed, every effort should be directed at getting the patient to the operating room as quickly as possible for fasciotomies.
- All further workup should be deferred until fasciotomies are complete, except workup that is needed for a potential life-threatening injury.
- There is little preoperative planning required for this component of the patient’s treatment.
- Radiographs should be reviewed to rule out fractures or dislocations; however, additional radiographs can be taken in the operating room after fasciotomies have been completed.
- Only essential preoperative workup should be done before the patient is taken to the operating room, and the case should certainly not be delayed for additional, nonessential radiographic workup.

Positioning

- The patient is usually positioned supine on the operating room table to facilitate fasciotomies. A small bump may be placed under the affected hip.
- The leg is prepared in a sterile fashion and a thigh tourniquet is applied but not inflated.

Approach

- Two separate techniques have been used for decompression of the lower leg compartments.
  - The two-incision technique is the most commonly used method, but a one-incision technique involving a lateral (perifibular) approach also exists.
  - The two-incision technique is more straightforward and requires less experience to ensure a complete compartment release and therefore is typically advocated.
  - Some have argued that the one-incision technique may be useful in defined anterior tibial artery injuries to help prevent loss of anterior skin.

DOUBLE-INCISION TECHNIQUE

Anterolateral Incision

- The anterolateral incision decompresses the anterior and lateral compartments.
  - The anterolateral incision is made halfway between the fibula and the crest of the tibia and lies just above the intermuscular septum dividing the anterior and lateral compartments (TECH FIG 1A).
  - Fasciotomies have also been accomplished through small incisions. However, we prefer using generous incisions to allow for full decompression of the compartments.
  - We recommend incisions that are typically at least 15 to 20 cm both medially and laterally.
  - A small transverse incision is performed to identify the intermuscular septum, after which scissors are used to split the fascia of the anterior and lateral compartments.
  - Care must be taken to avoid injuring the superficial peroneal nerve by making separate incisions in each compartment and not cutting the intermuscular septum (TECH FIG 1B–F).

Posteromedial Incision

- The posteromedial approach decompresses the superficial and deep posterior compartments.
  - The incision lies about 2 cm posterior to the posterior tibial margin (TECH FIG 2A).
  - Care is taken to avoid injury to the saphenous vein and nerve, which are retracted anteriorly.
  - A small transverse incision is made to allow visualization of the intermuscular septum between the deep and superficial posterior compartments, after which the fascia of each is incised longitudinally in line with the incision (TECH FIG 2B–E).
  - The deep posterior compartment is initially released distally, and then the scissors are oriented proximally through and under the soleus bridge.
  - It is crucial to release the soleus attachment to the tibia more than halfway. Also, the fascia over the posterior tibial muscle should be released.
  - One useful tip is to keep the tips of the scissors away from major neurovascular structures.
TECH FIG 1 • Lateral incision of the two-incision technique. A. The anterolateral incision is made halfway between the fibula and the tibial crest overlying the intermuscular septum dividing the anterior and lateral compartments. B. Close-up picture of the fasciotomy site after skin incision before fascia is open, showing the intermuscular septum between the lateral and anterior compartments as well as the course of the superficial peroneal nerve. C. With a knife, a small transverse incision is made over the intermuscular septum. Care is taken to avoid injury to the superficial peroneal nerve. D. The surgeon inserts the tips of the scissors into the small rent in the fascia, and keeping the tips of the scissors up and away from the superficial peroneal nerve, the surgeon incises the fascia over the anterior compartment distally. E. The scissors are turned with the tips proximally, and the fascia of the anterior compartment is released proximally. F. The tips of the scissors are then inserted into the rent created in the fascia of the lateral compartment. Keeping the tips of the scissors up and away from the superficial peroneal nerve, the surgeon releases the fascia over the lateral compartment proximal and distal.
ONE-INCISION TECHNIQUE

- The one-incision technique often requires more careful dissection around major neurovascular structures and can prove to be more challenging. For this reason it is less often used.
- A straight lateral incision is created that originates just posterior and parallel to the fibula at the level of the fibular head (protecting the peroneal nerve) to a point above the tip of the lateral malleolus (TECH FIG 3A).
- Posterior to the fibula, access is gained to the deep and superficial posterior compartments (TECH FIG 3B).
- The fascia between the soleus and flexor hallucis longus is identified distally and released proximally to the level of the soleus origin (TECH FIG 3C).12
- Anterior to the fibula, the anterior and lateral compartments are decompressed, taking care to avoid injury to the superficial peroneal nerve.
MUSCLE DÉBRIDEMENT

- Regardless of the choice of fasciotomy performed, devitalized muscle is débrided as necessary.
  - Muscle viability is ascertained by the presence of healthy color and the ability to contract when pinched gently or touched with the electrocautery.
  - Necrotic muscle serves no function and must be removed eventually, as it will form a culture medium for infection after fasciotomy.
  - Extensive débridement is not typically undertaken until the second look at 36 to 72 hours, when muscle viability is more readily determined.

- When fasciotomies are performed in the setting of fractures, the fractures are stabilized with either internal or external fixation, which eliminates the need for constricive casts and allows access for clinical examination, repeat pressure measurements, and wound care.
  - Fixation of fractures may trigger compartment syndromes through traction and reaming.

CLOSED OF FASCIOTOMIES

- Fasciotomies are typically not closed acutely because the skin itself can constrict muscle.
  - Most often fasciotomy wounds are either packed with moist dressings (TECH FIG 4A) or covered with a sterile vacuum sponge and kept under suction until the next débridement (TECH FIG 4B).
  - Following a lower leg fasciotomy, a useful technique has been the shoelace closure, which involves using a vessel loop and skin staples to gradually close large areas of gaping skin.
    - This allows gradual approximation of the skin edges over the course of several days, thus potentially obviating the need for a skin graft (TECH FIG 4C).

- If two surgical wounds are present, the surgeon should attempt to close the medial wound secondarily before the lateral.
  - The lateral side of the leg has better soft tissue coverage and consequently is easier to skin graft over if one of the wounds cannot be closed.
  - Sometimes small relaxing incisions around the fasciotomy wound can decrease the tension, enhancing the chance of healing (TECH FIG 4D).
POSTOPERATIVE CARE

Once decompressed, the extremity should be covered in a bulky dressing, splinted with the foot in neutral, and elevated above the level of the heart to promote venous drainage and reduce interstitial fluid.

- The foot should be splinted in neutral to prevent equinus contracture.
- The patient must be closely monitored for the systemic effects of compartment syndrome. See the discussion in the nonoperative section regarding administration of supplemental oxygen, intravenous hydration, mannitol, and hyperbaric oxygen.

In 1993 the average litigation award was $280,000 for eight cases of missed compartment syndrome (in all eight no compartment pressures were ever measured).24

PEARLS AND PITFALLS

- Medicolegal pitfalls: When in doubt, the surgeon should measure and document pressure in all compartments of the involved extremity. The surgeon should clearly document in the patient’s chart that the patient does not have compartment syndrome at this time if the clinical examination findings and pressures are negative.

- The surgeon should consider the possibility of equipment error.

- The surgeon should fully release all four compartments along with the soleal leash and posterior tibial fascia.

- No tight postoperative dressings should be used.

- Skin can cause increased pressure, so the surgeon should not close acutely.

- In 1993 the average litigation award was $280,000 for eight cases of missed compartment syndrome (in all eight no compartment pressures were ever measured).24

- Needles can be misplaced in tendons, fascia, or wrong compartment. All pressure readings must be interpreted within the context of the clinical presentation.

TECH FIG 4 • Closure of fasciotomies. A. Moist dressings covering the fasciotomy wound. B. Sterile vacuum system applied to the fasciotomy site, with vacuum suction set between 100 and 125 mm Hg. C. Small relaxing incisions made around the fasciotomy site to release tension and allow an easier closure. D. Bootlace technique for approximating the edges of a fasciotomy wound.
granulation and to lessen exposure of muscle and tendon. A flap may be needed if nerves, vessels, or bone is exposed.
- If delayed primary closure is planned, small relaxing incision can be done.
- Hyperbaric oxygen has been used because it reduces tissue edema through oxygen-induced vasoconstriction while maintaining and increasing oxygen perfusion.
- However, its opponents argue that hyperbaric oxygen leads to reperfusion injury following compartment syndrome.
- Other agents that have been found to affect recovery from compartment syndrome include allopurinol and oxypurinol, superoxide dismutase, deferoxamine, and penta fraction of hydroxyethyl starch. These agents are antioxidants and scavengers for damaging free radicals.

OUTCOMES
- Outcomes are generally poor if the compartment syndrome is diagnosed and treated in a delayed fashion. Results are better with earlier treatment.
- In a study by Sheridan et al, 50% of patients were decompressed within 12 hours and 50% were decompressed after 12 hours. Sixty-eight percent of the patients decompressed within 12 hours had normal leg function, whereas only 8% of the delayed group had normal function.
- If untreated, Volkmann ischemic contractures develop, leading to claw toes, weak dorsiflexors, sensory loss, chronic pain, and eventually amputation.

COMPLICATIONS
- Most patients (77%) complain of altered sensation within the margins of the wound. Fortyeight percent report dry, scaly skin, 33% pruritus, 30% discolored skin, 25% swollen extremity, 26% tethered scars, 13% recurrent ulcerations, 13% muscle herniation, 10% pain related to the wound, and 7% tethered tendons.
- Severe prolonged tissue ischemia resulting in necrosis of the muscles leads to fibrosis of the muscles and contracture that may continue over a period of several weeks.
- This is known as Volkmann ischemic contracture.
- The late sequelae of compartment syndrome are weak dorsiflexors, claw toes, sensory loss, chronic pain, and eventually amputation.
- Delayed fasciotomy after 12 hours has a reported infection rate of 46% and an amputation rate of 21%.
- The complication rate for delayed fasciotomies is also much higher (54%) than that for early fasciotomies (4.5%). Therefore, the current recommendation is that if the compartment syndrome has existed for more than 24 to 48 hours and the compartment pressures are not within 30 mm Hg of diastolic pressure, supportive treatment for acute renal failure should be considered, the skin is not violated, and plans should be made for a later reconstruction.

REFERENCES
In orthopedic surgery, the terms *pilon* and *plafond* have been loosely translated and interchangeably used to describe the weight-bearing portion of the distal tibial articular surface. These injuries account for about 1% of all lower extremity fractures and 5% to 10% of tibial fractures. Most orthopedic surgeons will encounter these injuries during the course of their practice; thus, a basic understanding of their characteristics and their management possibilities is important for any practicing orthopedist exposed to trauma. Open reduction with internal fixation (ORIF), even if through a limited approach, remains the basis by which most plafond fractures are operatively stabilized. As established by Ruëdi and Allgöwer, the goals of any surgery for plafond fractures should include precise articular reconstruction, restoration of extremity length and alignment, stable fracture fixation, and early joint motion. Despite its widespread application in this respect, open treatment presents some difficulties in the management of these fractures because it can compromise the thin soft tissue envelope surrounding the distal tibia. Modern techniques in fracture care are useful in minimizing complications associated with such open treatment in this unique location.

### ANATOMY

Pilon fractures involve the weight-bearing articular surface of the distal tibia. In about 90% of cases, there is an associated distal fibula fracture. The talus is predominantly cartilage-covered and sits in the ankle mortise beneath the tibial plafond. It is restrained medially and laterally by the malleoli.

### PATHOGENESIS

The mechanism of injury for articular fractures of the distal tibia usually involves some degree of axial compression as the dense talus impacts into the tibia’s distal articular surface. The distinction between fracture patterns is thus attributed to a number of other associated variables, such as the amount of rotational force involved, foot (talus) position during loading, bone quality, and energy of impact. Highly comminuted articular injuries usually occur because of high-energy axial loading forces, while spiral fractures with minimal articular injury are presumed to result from lower-energy rotational forces. True bending injuries are seen less commonly and may be caused by low- or high-energy causes. Despite the absence of a clear spectrum of injury severity, an estimation of the energy involved in a plafond fracture can be assumed from aspects other than the tibial fracture pattern itself (eg, history, soft tissue injury, associated injuries).

About 20% to 40% of plafond fractures are open, reflecting the severity of the injury and the need for aggressive soft tissue management.

Associated injuries should be carefully investigated because 5% to 10% of plafond fractures are bilateral, 30% of patients have ipsilateral lower extremity injuries, and 15% have injuries to the spine, pelvis, or upper extremities. Although a number of injury combinations are possible in the distal tibia, characteristic patterns can often be identified. Understanding the pattern of injury is critical to formulating an optimal treatment plan. Lower-energy metaphyseal or diaphyseal involvement of the tibia is spiral in nature with a cortical spike that can guide the reduction.

Metaphyseal comminution just above the articular plafond is frequently produced under high-energy axial loading, as the talus impacts into the corresponding weight-bearing surface of the tibia. In such injuries, the anterior plafond is often comminuted and impacted into the adjacent metaphysis. The degree of anterior articular plafond involvement is related to foot (talus) dorsiflexion at the time of impact.

The Orthopaedic Trauma Association’s Committee for Coding and Classification has developed its alphanumeric system from the AO/ASIF. This alphanumeric system is popular among fracture surgeons and is used in most current reports of fracture treatment.

Distal tibial fractures are designated as types 43-A, B, and C, with further subgrouping based on specific fracture characteristics (FIG 1).

- The three major types—A (extra-articular), B (partial articular), and C (intra-articular extension with complete separation between the articular fracture fragments and the tibial shaft)—are further divided into subgroups based on the amount of fracture comminution, articular depression, and overall displacement.
- Cole et al mapped 38 consecutive AO/OTA 43-C3 (complex articular) plafond fractures with CT scans and found that all plafond fractures in this category exited the tibiofibular joint laterally and at two separate locations medially to create a coronally oriented Y pattern with three major fragments (FIG 2A). There were also varying amounts of articular comminution anterolaterally or anteromedially (FIG 2B).

The three “major” plafond fragments seen in comminuted complete articular (AO/OTA 43-C) injuries can be described as follows:

- First, a posterior plafond fragment develops with a fracture line exiting 1 to 4 cm proximal to the articular surface (in partial articular injuries [AO/OTA 43-B], the posterior plafond often remains intact).
- An anterolateral plafond fracture fragment of varying size separates with its anteroinferior tibiofibular ligament attachment. This anterolateral tubercle of Chaput requires fixation to restore the anatomy and function of the syndesmosis complex.
- A medial malleolar fracture is identified as the third characteristic fragment.
In the Orthopedic Trauma Association's alphanumeric classification, distal tibia fractures (OTA 43) are grouped into types 43-A (extra-articular), 43-B (partial-articular), and 43-C (complete-articular). Each type is subgrouped based on specific fracture characteristics.
In contrast to high-energy patterns, rotational injuries (Fig 3) cause spiral fractures of the distal tibia and fibula originating at the articular level. Intra-articular injury, if present, is typically simple and without comminution or impaction.

**NATURAL HISTORY**

- On one end of the spectrum, high-energy vertical compression injuries result in comminuted articular fractures with compromised surrounding soft tissues. On the other end, low-energy rotational injuries with minimal axial compression produce more straightforward spiral fractures with less soft tissue damage and a more favorable prognosis.
- Where a particular fracture pattern falls within this spectrum can often predict the eventual outcome of the injury.
- Unfortunately, determining the outcomes from these fractures is not straightforward as existing classification systems fail to clearly distinguish the spectrum of injury, making a fair comparison of published outcomes difficult to achieve.
- What is clear is that the surgeon maintains an important role in affecting the final outcome of these injuries, principally by designing a treatment plan that accomplishes the surgical goals set out above while minimizing the risks of complications.
- Established variables that clearly affect outcome include avoiding complications while restoring a congruent articular surface and the axial alignment of that articular surface relative to the shaft.

**PATIENT HISTORY AND PHYSICAL FINDINGS**

- The injury history is usually clear and often involves a fall from heights, a motor vehicle crash, a motorcycle crash, or a sports injury. Occasionally, a patient will simply miss a step on stairs or a curb; this atypical history should initiate an investigation for osteoporosis.
- These patients are usually injured by high-energy means and should be evaluated as trauma patients and according to ATLS protocols.
- All associated injuries must be identified and formulated into the global treatment plan.
- Low-energy mechanisms should alert the surgeon to suspect osteoporosis and initiate an osteoporosis evaluation.
Comorbidities such as diabetes mellitus, vascular disease, tobacco use, chronic immune or inflammatory diseases, and others may affect treatment and risk stratification. The medication profile should be assessed for blood thinners, anti-inflammatories, and others that may affect surgical risk or bone metabolism.

A meticulous examination with special attention to soft tissue and neurovascular status is important in the evaluation and classification of these fractures (Tables 1 and 2).

With wound complication rates having a historic potential of 50%, recognition and appropriate management of the soft tissue injury cannot be overemphasized.

The physician should inspect for wounds, swelling, blisters, ischemic skin, and chronic skin and vascular changes.

The physician should identify open fractures and establish the “personality” of the injury.

Areas of swelling or ecchymosis, breaks in the integument, and the presence or absence of fracture blisters should be identified and documented preoperatively.

A careful vascular examination is important in evaluating patients with high-energy pilon injuries, as arterial compromise appears to be more common than previously appreciated (which may help explain the relatively high complication rates seen with early ORIF).

Findings of vascular compromise may be subtle (such as a one-vessel injury [eg, anterior tibial artery]) owing to collateral or retrograde flow patterns. Arterial compression testing (Allen test) about the ankle or the addition of angiography to CT may be a useful tool to further evaluate the local vasculature.

Rarely, compartment syndrome may also occur, creating the need for urgent operative intervention.

The diagnosis of tibial plafond fracture is initially evaluated with three radiographic views of the ankle (anteroposterior [AP], mortise, and lateral; **FIG 4A,B**).

These views should be repeated after all “reductions,” including application of temporizing external fixation.

CT scans have been clearly shown to improve a surgeon’s understanding of the injury (**FIG 4C**) and are critical to preoperative planning for complex injuries.\(^1^5\)

For displaced, comminuted pilon fractures, the best time to obtain a CT scan is after temporizing external fixation is performed (**FIG 4D**), when the fracture is brought out to length with traction. This tends to grossly reduce many parts of the fracture, making the pathoanatomy of the injury more understandable (**FIG 4E,F**).

The addition of angiography to CT is sometimes useful for assessing the arterial tree of the distal leg before plafond reconstruction, if vascular injury is suspected (**FIG 4G**). Occult vascular injuries, especially of the anterior tibial artery, are not uncommon in patients with high-energy plafond fractures.

### Differential Diagnosis

- Tibial shaft fracture
- Ankle fracture or dislocation
- Talus fracture

### Nonoperative Management

Nonoperative treatment should be reserved for nondisplaced or minimally displaced fractures that are determined to be stable and have little comminution and soft tissue injury.

This scenario is uncommon, however, as the amount of energy necessary to fracture the tibial plafond typically results in significant fracture displacement and resultant instability.

Some consideration may be given to nonoperative treatment in the infirm or neuropathic patient, although the risks of splinting or casting are often greater than for operative treatment.

Attempts at casting or splinting unstable plafond fractures in patients considered to be poor candidates for operative treatment (eg, elderly, diabetes, vasculopathy) are fraught with risks for progressive deformity, skin breakdown, and amputation.

The presence of other musculoskeletal injuries becomes a strong indication for surgical treatment to the tibia as surgical stabilization may allow for easier mobilization and rehabilitation.

Reasonable nonoperative treatment options include non-weight bearing with casting or bracing until radiographic signs of healing are visualized.

Regular follow-up radiographic vigilance is recommended to ensure that articular congruity and axial alignment of the lower leg remain satisfactory.

Protected weight bearing must be individualized in each case, but usually at least 10 to 12 weeks is necessary to safely expect alignment to be maintained.

### Surgical Management

Displaced tibial plafond fractures generally require surgery. ORIF is the preferred method of treatment for such displaced fractures to achieve the goals previously outlined by Ruédi and Allgöwer.\(^1^1\)
Preoperative Planning

Understanding the personality of the injury, including soft tissue problems, patient problems, and the fracture configuration, is critical to formulating an optimal treatment plan.

Preoperative planning allows the surgeon to work through the case “on paper” while minimizing risk and often preventing unnecessary delays during the surgery.

A preoperative tracing (FIG 5) can help with instrumentation needs, surgical approaches, anticipated reduction methods, and implant strategies (selection and placement).

CT data often allow the surgeon to choose the optimal approach to address the articular pathology and apply implants (eg, anteromedial versus anterolateral approaches for most AO/OTA 43-C fractures).

Positioning

Most pilon fractures are approached anteriorly; thus, the patient is typically positioned supine on a radiolucent table.

A roll behind the hip may help control external rotation of the leg during surgery.

Tourniquet control is often helpful to allow for visualization, particularly of the ankle joint.

The preparation and draping is carried above the knee to make the Gerdy tubercle region available if any autogenous bone graft is needed.

The temporary external fixation pins are incorporated into the preparation and draping. These pins are used intraoperatively for distraction through the external fixator itself or, alternatively, through a universal (femoral) distractor. The pins are isolated with Ioban.

Such distraction is helpful in obtaining reduction and provisional stabilization of the articular surface and can also be used during initial plate placement and screw fixation.

For posteromedial approaches the patient may still be positioned supine, but in this case the surgeon may desire the leg to be externally rotated, and a bump under the contralateral hip may be helpful.

When the posterolateral approach is used, the patient is best positioned prone (or lateral) to allow the surgeon comfortable access to the posterior leg.

Approach

Although historically a single “utilitarian” approach was popular in the reconstruction of the tibial plafond, a variety of surgical approaches are currently used to treat these fractures (FIG 6).

In principle, less dissection and soft tissue retraction, as well as optimal implant placement, should be possible using more direct approaches.

As with other complex injuries, the selection of an approach that addresses the personality of each injury is recommended for plafond fractures.

These more customized approaches should adhere to the following principles:

- Effective soft tissue handling
- Maintenance of a reasonable skin bridge between incisions (especially if these incisions are long or extensile)
- Placing skin incisions directly over bone should be avoided if possible. Thus, if skin problems occur, resultant tissue defects can be reconstructed with a simple skin graft or fasciocutaneous flap as opposed to a free soft tissue transfer.

Howard et al recently reported a series of 46 plafond fractures in 42 patients in which 106 skin incisions were used, creating 60 skin bridges. The mean skin bridge size was 5.9 cm; only 16% were greater than 7 cm. All incisions other than two healed uneventfully, and no deep infections or skin bridge compromises were recorded.

FIG 6 • Approaches to the tibial plafond are probably best tailored to match the injury pattern. More than 90% of plafond fractures are well approached anteriorly (anteromedially or anterolaterally), but other approaches are sometimes useful.

ANTEROMEDIAL APPROACH

The traditional “AO,” or anteromedial, approach to the tibial pilon uses an anteromedial incision directed longitudinally a centimeter or so lateral to the anterior tibial crest and crossing in a gentle oblique fashion over the tibialis anterior tendon to allow for careful medial column exposure (TECH FIG 1).

We use this anteromedial approach for injuries in which the bulk of the articular injury is medial and the anterior cortex fracture propagates medially along the distal tibia.

Accessing the far lateral joint surface using this approach requires a fairly vigorous retraction of the anterior ankle soft tissues (a small anterolateral incision can sometimes be used concomitantly with the anteromedial approach to reduce or stabilize the anterolateral fragment).

TECH FIG 1 • A–C. Imaging of 43-C3 plafond injury with anteromedial cortical split allowing best access to injury through anteromedial approach. (continued)
- Dissection is full thickness and carried medial to the tibialis anterior tendon so as not to create multiple tissue dissection planes.
- Careful handling of the subcutaneous tissue is mandatory.
- The paratenon of the tibialis anterior tendon should not be disrupted.
- Extensive periosteal stripping of fracture fragments is avoided and fragments are carefully hinged on their soft tissue attachments to preserve their vascularity.
- Hinging open the anterior fragments like a book using a small lamina spreader reveals the involvement and displacement of the central and posterior articular plafond and metaphysis.
- Once the extent of the fracture is appreciated, reduction and fixation can be performed.

Many surgeons have recently begun using an anterolateral approach for plafond injuries in which the essential features of the injury are more laterally located (TECH FIG 2).
- This approach to the ankle has been nicely described by Herscovici et al.5
- The dissection proceeds just lateral to the extensor digitorum longus and peroneus tertius. The anterior tibial neurovascular bundle remains medial.
- Superficial peroneal nerve branches will be encountered and should be protected.
- If a narrow skin bridge occurs between this approach and the fibular incision, this approach should be kept short (eg, 4 to 5 cm) and used for the articular reduction.

In some cases, the articular injury can be addressed through a small anterolateral approach and attachment of the reconstructed articular segment to the intact diaphysis is accomplished by inserting an anterolateral submuscular or anteromedial subcutaneous plate.
- Proximal fixation can then be applied in a more “open” manner outside the zone of injury.
- Alternatively, if the fibula and plafond are being repaired at the same operative visit, a single gently curved skin incision placed over the syndesmosis can be used to access both bones.
- Here, too, the superficial peroneal nerve will be encountered and should be protected.
**TECH FIG 2 • A–C.** Imaging of 43-C3 pilon fracture with mostly anterolateral injury pathology. **D.** Anterolateral approach. This is a modification of Bohler’s incision, in line with the fourth metatarsal and extending proximally between the tibia and fibula.
POSTEROMEDIAL AND POSTEROLATERAL APPROACHES

- Additional approaches include the posteromedial and posterolateral approaches.
  - These methods are not commonly employed but may be most useful in combination with other approaches.
  - Both allow for minimal access to the articular surface such that complex intra-articular injuries are not well addressed through these approaches alone.
  - They are effective, however, for aiding in reduction of hard-to-reduce posterior fragments and applying small buttress plates that may improve the fixation stability of individual posterior articular segments.
- The posteromedial approach uses a skin incision posterior to the medial face of the tibia and requires mobilization of (and inherent risk to) the posterior tibial tendon and posterior tibial neurovascular bundle (see Fig 6).
  - There are essentially three intervals to access the posteromedial tibia via this approach, depending on the fracture configuration and how far posterior the surgeon must reach:
    - Anterior to the posterior tibial tendon
    - Between the posterior tibial tendon and the flexor digitorum communis tendons
    - Between the flexor digitorum communis tendon and the posterior tibial neurovascular bundle
  - The retinaculum is incised and repaired at the time of wound closure.
- The posterolateral approach to the distal tibia creates some logistical problems as the patient is best positioned prone (or lateral).
  - The skin incision is placed 1 to 2 cm posterior to a standard fibular incision and can easily be combined with fibular repair.
  - This approach uses the interval between the peroneal tendons and flexor hallucis longus (TECH FIG 3). Fairly extensile and safe exposure to the posterior aspect of the distal tibia is possible using this approach.
  - The posterior cortex fracture is usually fairly simple and can be used to gauge reduction. Small or mini-fragment buttress plates are often useful here.

TECH FIG 3 • The posterolateral approach uses the interval between the peroneal and extensor hallucis longus muscles and allows for wide exposure of the posterior distal tibia. Access to the fibula can also be easily gained through this incision.

REDUCTION AND FIXATION OF THE FIBULA

- Consideration about placing and timing of the fibular repair must be thoughtful to prevent limiting approaches to the tibia.
- The fibula is often reduced and fixed first to indirectly reduce the tibia fracture. It is sometimes repaired at the time of the external fixator application during staged treatment.
- In this context, the fibula must be well reduced or the tibial reduction will be impaired.
- If staged treatment is employed with external fixation applied at a referring hospital, most tertiary centers prefer the fibula to remain unfixed, thus allowing for maximal flexibility for the surgeon providing definitive treatment.
- If separate approaches are to be used for tibial and fibular repair, the fibular incision is often made more posteriorly than for most fibular repairs to maintain an optimal distance from anticipated anteromedial or anterolateral incisions.
- The posterolateral approach to the distal fibula is also a good option because it falls between the major distributions of the sural and superficial peroneal nerves. The patient can be discharged and remain mobile for daily activities while awaiting soft tissue improvement.
ARTICULAR REDUCTION AND FIXATION OF THE PILON

- The first priority in ORIF of complex articular injuries, such as with pilon fractures, is accurate realignment of the joint surface and rigid internal fixation.
- Once stabilized, the articular segment can then be attached to the tibial diaphysis through open or minimally invasive plating (or external fixation).
- Many times, reduction of the articular segment and reduction of the metadiaphysis are performed simultaneously.
- Nonreconstructable loose bodies are débrided.
- Regardless of the approach chosen as the most appropriate by the surgeon, careful and precise articular reconstruction must be achieved.

- Less than 2 mm of articular incongruity is typically considered acceptable.
- With joint distraction (femoral distractor or external fixator), the anterior two thirds of the joint should be readily accessible through an anterior approach.
- A lamina spreader is often helpful for “booking open” vertical cortical fractures to access impacted articular fragments (TECH FIG 4A–D).
- One articular fragment is reconstructed to another until all important fragments are addressed.
- Sometimes the talar dome can be used as a template for articular plafond reduction.

**TECH FIG 4** • **A–C.** Imaging of a typical 43-A3 plafond injury. (The a and b in C correspond to the fragment labeling in E.) **D.** The anterior cortical split is opened like a book and held with a lamina spreader. Dissection is limited to that necessary for reduction and plating. Direct visualization of the anterior two thirds of the joint is typically available and may be enhanced with use of a distractor (or external fixator). **E.** In some extreme cases such as this, major articular fragments are reconstructed with Kirschner wires, mini-fragment screws, or absorbable pins on the back table. **F.** Clamps and provisional fixation with Kirschner wires can be placed through the wounds or percutaneously (carefully).
This reconstruction should be provisionally stabilized with multiple Kirschner wire fixation (TECH FIG 4E).

- Direct visualization of the joint and radiographic guidance should be critically evaluated.
- The posterior plafond can be difficult to reduce from an anterior-based exposure. Ankle positioning often affects the position of this fragment.
- Sometimes, wire joystick manipulation or the use of a sharp pick or careful pointed clamp application is necessary to obtain an adequate reduction of posterior fragments.
- Posterior approaches may also be necessary, especially if displaced posterior fracture lines exit "low" (ie, they do not extend proximally).
- Provisional wires can be used as guidewires for cannulated screws if needed.
- Small and mini-fragment screws are useful and should be placed before removal of the provisional wires.
- Once articular reconstruction is complete, the disimpressed metaphyseal area is evaluated for bone grafting needs.
- For autograft, the Gerdy tubercle region is easily accessible and less painful than the iliac crest and can provide an adequate amount of graft in most cases.
- If additional graft is required or the patient does not want to risk autograft morbidity, a synthetic graft or allograft chips are usually a suitable alternative (operative consent should reflect the potential for graft use).

### EXTRA-ARTICULAR (METAPHYSEAL) REDUCTION AND FIXATION OF THE PILON

- Once the articular reduction is completed, reattaching the distal articular segment to the diaphysis is accomplished (in many cases, this is done simultaneously).
- We prefer plate fixation, although some surgeons use external fixation after a limited ORIF of the articular surface.
- Currently, “anatomically” contoured low-profile, small-fragment plates (with locking capability) designed for the distal tibia are available from most implant vendors.
- The anatomic design of these implants affords a satisfactory match to the anteromedial or anterolateral (TECH FIG 5) surface of the distal tibia.
- Traditionally, we have used the small fragment plates, which allow easy and precise contouring for an appropriate bony fit.
- Nonlocking screws are used first to bring the plate in close apposition to bone to minimize the plate’s prominence against the soft tissues.
- Subsequent insertion of locking screws, creating a “hybrid” internal fixation construct, is determined based on factors such as bone quality, comminution, and expected time to healing.
- An anterior plate location is often best for neutralization or buttressing of complex intra-articular fractures.

**TECH FIG 5** • A,B. Lag screws are used and anterior plating is performed to optimize fixation of the articular segment with a raft of anterior–posterior screws. Autograft from the tubercle of Gerdy was used above the disimpressed articular surface, but allograft or substitutes may be used. (continued)
WOUND CLOSURE AND CARE

- Once intraoperative radiographs reveal a satisfactory reduction and position of implants, the incision is closed.
- Retinacular layers are reapproximated to cover the underlying bone and implants.
- A drain may be considered to minimize pressure on the incision line from fluid accumulation under the wound.
- The subcutaneous layer is closed with an absorbable suture before skin closure.
- We use fine (4-0) nylon interrupted sutures and atraumatic soft tissue handling during wound closure (TECH FIG 6).
- Closing the anteromedial incision without tension is critically important. Any substantial tension on the anterior skin edges after closure will likely result in some degree of soft tissue necrosis. Rarely, accomplishing this step may require relaxation of the lateral incision or a return trip to the operating room for delayed closure.
- A lightly compressive bulky dressing and splint are applied with the ankle in neutral position.
- Finally, elevation is resumed before leaving the operating room to minimize swelling.

PEARLS AND PITFALLS

Minimizing risk for major complications

- Before modern methods of soft tissue handling, open treatment of high-energy tibial plafond fractures was directly associated with high complication rates (about 50%).
- Many of these complications are preventable; thus, tibial pilon fractures present the orthopedic surgeon with a real opportunity to influence a patient’s ultimate outcome.
- Contemporary fracture treatment principles (eg, staged treatment protocols, tailored surgical approaches, careful soft tissue handling, indirect reduction, and biologic fixation) have reduced the rate of complications to an acceptable level (about 0% to 10%) for these fractures.
### Surgical goals
- As established by Rüedi and Allgöwer, the goals of surgery for pilon fractures include precise articular reconstruction, restoration of extremity length and alignment, stable fracture fixation, and early joint motion.
- The avoidance of complications is critical to consistently achieving optimal clinical results.

### Soft tissue management
- The soft tissues must be quiescent at the time of plafond open reduction and internal fixation.
- Staged treatment protocols, tailored surgical approaches, careful soft tissue handling, and indirect reduction should be used routinely for these injuries.

### Articular reduction tricks
- The articular reduction is of paramount importance and is usually performed first, followed by the metaphyseal–diaphyseal reduction.
- Longitudinal traction with an external fixator or femoral distractor allows for indirect fracture reduction and joint visualization.
- Articular fragments may be disimpacted with small osteotomes or elevators. These fragments should be kept as thick as possible, and voids created by disimpaction should usually be grafted.
- A well-positioned talar dome may be useful as a template to reduce articular fragments.
- Multiple Kirschner wires and carefully placed pointed clamps may help in gaining and maintaining reduction.
- Fracture reduction should be carefully scrutinized using direct visualization and radiography before and after fixation so that changes can be made before definitive fixation or leaving the operating room.

### Metaphyseal reduction tricks
- Often reducing the joint fragments will simultaneously realign the metaphysis.
- Pointed clamps, small push plates, and lag screws are very useful for the metaphyseal reduction.
- Axial alignment must be carefully scrutinized clinically and radiographically.
- A well-repaired fibula is an excellent guide for restoring tibial length.

### Fixation problems
- 2.4-, 2.7-, and 3.5-mm lag screws and occasionally absorbable pins are useful for fixation of the articular fragments. These are often placed in subchondral bone to gain optimal stability of osteochondral fragments.
- Anatomically contoured pilon plates with locking capability are nice tools for use in complete articular injuries or osteoporotic bone but are not always necessary (or desirable).

### POSTOPERATIVE CARE
- Elevation of the extremity should continue for the next few weeks to protect the incisions.
- Patient education is important to maximize understanding of wound risks and compliance with elevation and other postoperative treatments.
- Aggressive respiratory care and supplemental oxygen are continued until the patient is fully awake and off intravenous narcotics (respiratory depressants).
- Immobilization is maintained for about 10 to 14 days or until the incisions have healed adequately.
- At the time of suture removal, ankle range-of-motion exercises are taught, and the limb is placed in a removable fracture brace.
- Strict non-weight bearing is continued, with advancement in weight bearing made when radiographic evidence of fracture consolidation is adequate, typically at 10 to 12 weeks after surgery.

### OUTCOMES
- The philosophy for open reduction and rigid internal fixation of plafond fractures is a direct extension of Rüedi and Allgöwer’s original recommendations.11
- Historically, early poor results with ORIF were primarily related to the disruption of the soft tissue envelope and not the fixation of the bony fracture itself.7,14
- These failures were the result of the inherent fragility of the thin soft tissue envelope in this area, misunderstandings of the soft tissue injury severity, overly aggressive soft tissue stripping during surgery, and the use of prominent, large fragment implants for stabilization.
- More modern techniques of plafond fracture management have led to much more satisfactory complication rates for pilon fractures.
- Sirkin et al13 retrospectively analyzed a staged protocol for management of 56 C-type plafond fractures treated using a protocol of immediate (within 24 hours) stabilization of the fibula fracture with temporary spanning external fixation of the tibia across the ankle joint. Formal open reconstruction of the tibial fracture with plating was performed when soft tissues normalized (average 13 days). Three patients developed deep infections (6%) and five patients had superficial necrosis that was well treated with local wound care and oral antibiotics.
- Patterson and Cole9 published results of a similar two-staged technique for the treatment of C3 plafond fractures. Twenty-one patients underwent early fibular fixation and construction of the tibial fracture with plating was performed when soft tissues normalized (average 24 days). Patients underwent ORIF of the plafond fractures. There were no infections or soft tissue complications.
- There are a few limited studies that have compared staged ORIF to other methods for treating tibial plafond fractures.
- Blauth et al2 retrospectively compared results of three different management protocols for severe plafond fractures (92% 43-C fractures):
  - Primary ORIF (n = 15, reserved for patients with closed fractures without severe soft tissue trauma)
  - Primary minimally invasive osteosynthesis of the articular surface with long-term (minimum of 4 weeks) transarticular external fixation of the ankle (n = 28)
  - Two-stage procedure with primary minimally invasive osteosynthesis of the articular surface and ankle-spanning
external fixation, followed by staged subcutaneous plat- 
ing (n = 8).
- While the incidence of wound infection did not differ significantly among the three groups, this study found that patients who had undergone two-stage surgery did better in terms of pain, ankle motion, activities of daily living, and the need for secondary arthrodesis compared to the other groups.
- Babis et al\(^1\) retrospectively compared 50 tibial plafond fractures treated by ORIF to 17 patients treated with minimally invasive osteosynthesis or external fixation. They found that three parameters significantly influenced results: the severity of fracture, the quality of surgical reduction, and the procedure by which the fracture was managed (ORIF did better).
- Harris et al\(^4\) compared functional outcomes after operative treatment of 43-B or C plafond fractures with ORIF (n = 63) versus limited open articular reduction and wire ring external fixation (n = 16). The greatest impairment in outcome was noted after type C3 fractures regardless of the method of treatment employed. ORIF was associated with fewer complications and less posttraumatic arthritis than external fixation, but this finding possibly reflected a selection bias, as open injuries and the more severely comminuted fractures were all managed with external fixation.
- Two studies have reported intermediate or long-term patient outcomes after ORIF of tibial plafond fractures.
- Sands et al\(^12\) reported on 30 patients who completed the SF-36 more than 18 months after ORIF of a tibial plafond fracture. There were deficits in every SF-36 subcategory, with the largest differences in outcomes seen in the areas of physical function and physical role function.
- Pollak et al\(^10\) similarly evaluated 80 patients with the SF-36 more than 2 years after ORIF of a pilon injury. They also found diminished scores in all eight functional domains of the SF-36, including markedly abnormal scores for physical function, physical role function, and bodily pain. They also reported that 35% of patients reported substantial ankle stiffness, 29% had persistent swelling, and 33% described ongoing pain. Of the participants who had been employed before the injury, 43% were not working at final follow-up.

**COMPLICATIONS**

- Tibial pilon fractures are often complex injuries that have a high potential for complications if not managed thoughtfully.
- As many of these complications are somewhat preventable, tibial plafond fractures present the orthopedic surgeon with an opportunity to improve a patient’s ultimate outcome.
- While we cannot alter the severity of a particular injury, appropriate surgical timing and soft tissue handling, along with exact articular reduction and stable fixation to allow for early motion, offer the best chance of obtaining good results with few complications for patients with these fractures.
- Wound problems resulting from these procedures should be treated aggressively to prevent deep infection.
  - Superficial marginal wound necrosis can be successfully managed with local wound care with or without oral antibiotics.
  - Full-thickness necrosis (eschar) can be followed as well in reliable patients who can be followed closely and educated to return immediately for any wound problems. Once the eschar begins to detach or drain (becomes “unstable” eschar), it will need to be removed immediately and débrided and antibiotics given. If healing beneath the eschar is inadequate at the time of its unroofing, the patient may require formal débridement and soft tissue coverage with a simple skin graft, fasciocutaneoues flap, or free soft tissue transfer, depending on the area and size of the wound and how much “biology” will be necessary to aid healing and prevent infection.
  - Anteromedial wounds of this sort are more problematic than anterolateral wounds or others, because the underlying tibia and fracture will be exposed in the anteromedial case.
  - Established deep infection is a limb-threatening problem and usually requires intravenous antibiotics, staged surgeries including external fixation support, soft tissue coverage (often through free-tissue transfer), and possibly late bone grafting.
  - Importantly, not all patients are good candidates for such complex reconstructive procedures. In these cases, early below-the-knee amputation is a useful means for restoring predictable function in an expeditious manner.
  - Malunion typically occurs in varus and usually occurs if malalignment is accepted or unrecognized or union is not achieved or fixation fails.
  - Prevention is important and should focus on providing adequate initial and ongoing medial column support against an intact, plated, or healed fibula.
  - Some surgeons avoid fixation of the fibula entirely. This method is typically coupled with external fixation for the tibia fracture after limited open articular reconstruction.
  - Avoiding fibular stabilization, however, does not convincingly decrease and perhaps even increases the chance of angular deformity. Also, maintaining appropriate length is more difficult with the use of external fixation alone.
  - Malalignment of the tibia or fibula may adversely affect ankle function and result in painful ankle arthrosis.
  - Most authors use less than 5 degrees of varus–valgus and less than 5 or 10 degrees of recurvatum–procurvatum as a limit for acceptable alignment.
  - Malunion surgery is typically associated with adjustment of the fixation and requires careful preoperative planning and perhaps referral to a surgeon with experience in posttraumatic reconstruction.
  - Nonunion or delayed union occurs in about 5% or more of patients and may occur in combination with malalignment.
    - Injury and host factors are implicated in problems with union of the tibial pilon.
    - Significant metaphyseal comminution, open fractures, and bone loss are factors prone to causing healing problems; adju nctive measures should be considered in these cases.
    - Smoking cessation and avoidance of nonsteroidal anti-inflammatory medications should be routinely discussed with patients to decrease the likelihood of these complications.
    - Immediate or early staged (4 to 8 weeks) bone grafting may advance tibial metaphyseal healing in high-risk fractures. External bone stimulation can also be considered early (for acceleration of fresh fracture healing) or late (as an adjunct to nonunion surgery) in the treatment course.
    - Treatment of an established distal tibial nonunion requires a comprehensive plan including consideration of the soft tissues, local biology and mechanics, presence of infection, condition of the ankle joint, and others.
Repair frequently requires realignment of the limb axis, followed by rigid fixation with or without bone grafting. Posttraumatic arthritis should be addressed by an initial course of conservative care. Ankle arthrodesis (method by surgeon preference) is often chosen once nonoperative treatment measures have been exhausted. Recent advances in total ankle arthroplasty may hold promise in carefully selected patients, but this is not currently recommended. Rarely, a primary arthrodesis is considered for limb salvage in severe fractures in which the articular surface cannot be salvaged. The combination of metaphyseal nonunion and ankle arthritis is particularly difficult because the intercalary segment of tibia (between the nonunion site and the ankle joint) is often small and of poor bone quality. Treatment options for this condition include amputation (especially if infection is present), resection with distraction osteogenesis, or internal fixation spanning both the nonunion and arthritic ankle along with bone grafting.

REFERENCES
DEFINITION

- The ankle is a modified hinge joint, which relies on a congruently reduced mortise to provide optimal function.
- Maintenance of normal tibiotalar contact is essential if one is to maintain function.
- Surgical treatment of displaced, unstable ankle fractures centers on anatomic restoration of the bony and ligamentous relationships that make up the ankle mortise.
- This chapter will focus on the treatment of a specific pattern of injury to the ankle, specifically the bimalleolar fracture pattern.

ANATOMY

- The anatomy of the distal tibia and ankle joint must be taken into account when considering ankle fractures. As the tibial shaft flares in the supramalleolar region, the dense cortical bone changes to metaphyseal cancellous bone (FIG 1A).
- The shape of the tibial articular surface is concave, with distal extension of the anterior and posterior lips.
  - This surface has been called the tibial plafond, which is French for ceiling.
  - The talar dome is wedge-shaped and sits within the mortise. It is wider anteriorly than posteriorly.
  - The medial end of the tibia is the medial malleolus.
  - The medial malleolus is composed of the anterior and posterior colliculi, separated by the intercollicular groove (FIG 1B).
  - The anterior colliculus is the narrower and most distal portion of the medial malleolus and serves as the origin of the superficial deltoid ligaments.
  - The intercollicular groove and the posterior colliculus, which is broader than the anterior colliculus, provide the origin of the deep deltoid ligaments.
  - The insertions of the deltoid ligaments (medial tubercle of the talus, navicular tuberosity, and sustentaculum tali) can also be considered part of the medial malleolar osteoligamentous complex.
  - The lateral malleolus is the distal end of the fibula. It extends about 1 cm distal and posterior compared to the medial malleolus.
  - The syndesmotic ligament complex unites the distal fibula with the distal tibia. The following ligaments make up the syndesmotic complex: the anteroinferior tibiofibular ligament, the posteroinferior tibiofibular ligament, the inferior transverse ligament, and the interosseous ligament (FIG 1C).

PATHOGENESIS

- The majority of bimalleolar ankle fractures are secondary to rotation of the body about a supinated or pronated foot. They are best defined by the classification of Lague-Hansen (FIG 2).
- The supination-external rotation pattern of ankle fracture is divided into four stages.
- The stage 1 injury is tearing of the anterior inferior tibiofibular ligaments.
- As the external rotation force continues laterally, a spiral fracture of the fibula occurs. On lateral radiograph, the fracture line will pass from the anteroinferior cortex to the posterolateral cortex.
- The third stage occurs when the posteroinferior tibiofibular ligaments avulse or fracture off the posterior malleolus.
- The final stage results in a medial malleolar osteoligamentous complex injury with either a deep deltoid ligament tear or a fracture of the medial malleolus.
- The pronation-external rotation variant also has four stages. Because of the pronated position of the foot at injury, however, the medial structures are injured in the early stages.
- The fibula fracture pattern seen with this mechanism is usually supras Syndesmotic, and the fracture pattern is an anterolateral-to-posterolateral fracture line as seen on the lateral radiograph.
- The supination-adduction pattern is heralded by a low transverse fibular fracture and a vertical shearing pattern medially. This pattern is also associated with tibial plafond impaction.
- Finally, the pronation-abduction pattern is identified by the avulsion of the medial malleolus and a transverse or laterally comminuted fibular fracture above the syndesmosis secondary to a direct bending moment.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Most patients who present with ankle pain following trauma will describe a twisting type of injury. Less frequently they will report a direct blow to the ankle.
- Proper medical history should include the patient’s current comorbid medical conditions, such as peripheral vascular disease, diabetes, or peripheral neuropathy.
- Physical examination should center on inspection, palpation, and neurovascular examination.
  - It is important to note any gross deformity, which may signify dislocation. If dislocation is present, the ankle should be reduced and splinted as soon as possible to prevent skin tenting and neurovascular compromise.
  - Inspection for any open wound about the ankle is critical as well. Open fractures imply a surgical urgency. Swelling, ecchymosis, and tenderness about the malleolus should be recorded.
  - For patients with a supination-external rotation pattern isolated fibula fracture who present with an intact mortise, the gravity stress examination can be revealing. More than 5 mm of medial clear space widening in association with a lateral malleolar fracture signifies an unstable pattern.
  - Pain at the ankle along the syndesmosis during a squeeze test implies injury to the syndesmosis.
  - The proximal fibula, knee, and tibia should also be examined. Palpation of pulses, detection of capillary refill, and a
Part 2 PELVIS AND LOWER EXTREMITY TRAUMA • Section IV FOOT AND ANKLE

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Radiographic examination includes the ankle trauma series: anteroposterior (AP), lateral, and mortise view (FIG 3A–C).
- In patients with isolated lateral malleolar fractures with clinical signs of medial injury, or if there is any question of ankle stability in a supination–external rotation fracture pattern, a manual external rotation stress radiograph should be obtained to assess for instability.
  - The tibia is held internally rotated 15 degrees with the ankle in dorsiflexion to produce a gentle external rotation moment at the ankle under fluoroscopy (FIG 3D).
  - More than 5 mm of medial clear space widening in association with a lateral malleolar fracture signifies an unstable pattern (FIG 3E).
  - If clinically warranted, full-length tibia–fibula radiographs should be obtained.
- Restoration of medial ankle stability depends on the size and location of the medial malleolar fragment.
  - The size of the medial fragment is key to stability.
  - Anterior collicular fractures will have only the superficial deltoid attached. In about 25% of supination–external rotation type 4 injuries there will be an associated deep deltoid rupture. Thus, fixation of this fragment will not enhance stability.
  - The lateral radiograph is the key. If the fragment is greater than 2.8 cm wide, the deep deltoid will be attached and stability is restored. If the fragment is less than 1.7 cm wide, then stability is not restored with fixation. For fractures in between, an intraoperative external rotation stress examination should be performed following malleolar fixation.
- CT scanning may be helpful in assessing posterior malleolar fragment size in rotational ankle fractures.
- MRI may have some utility if there is an isolated lateral malleolus fracture with signs of medial injury and an equivocal stress examination.
NONOPERATIVE MANAGEMENT

- Ankle fractures in which the ankle mortise remains stable can be treated nonoperatively.
- Isolated lateral malleolus fractures without evidence of medial-sided injury are considered supination external rotation type 2 injuries and can be treated with functional bracing and weight bearing as tolerated.
- Unstable patterns such as supination-external rotation type 4, either ligamentous or a true bimalleolar or trimalleolar ankle fracture, can also be treated nonoperatively in patients who are poor surgical candidates (e.g., insulin-dependent diabetics), who have severe soft tissue problems, or who do not wish to undergo surgical stabilization.
- If nonoperative treatment is chosen, it is crucial to ensure anatomic mortise reduction throughout treatment until healing.
- Unstable injuries should be treated in a well-molded short-leg cast and checked on a weekly basis to ensure continued mortise reduction.

SURGICAL MANAGEMENT

- Any fracture of the ankle in which there is residual talar tilt or talar subluxation such that the ankle mortise is not anatomically reduced is an indication for surgical stabilization.

Preoperative Planning

- Surgical anatomy should be reviewed prior to entering the operating room, including the bony and ligamentous structures.
  - The neurovascular anatomy about the ankle should be reviewed, including the course of the saphenous vein medially and the superficial peroneal nerve laterally.
- Equipment to be used includes a small fragment plate and screw set, large pelvic reduction clamps, small-diameter Kirschner wires, and 3.5- to 4.0-mm cannulated screw sets. If
the nature of the fracture is still in question, radiographic stress examination may be performed under anesthesia.

**Positioning**
- The patient is positioned supine with a small bump under the ipsilateral hip to ease access to the fibula.
- A pneumatic tourniquet can be applied to the affected thigh if desired for use during the surgical procedure. The affected limb is prepared and draped free.
- The bump may be removed after lateral fixation for easier access to the medial side.
- In rare cases, if a posterior approach is chosen, the patient may be placed in the prone position to allow access to the posterior tibia via the posterolateral approach.

**Approach**
- The fibula is approached via a direct lateral incision.
- The medial malleolus is approached via a gently curved anteromedial incision.
- Direct access to the posterior malleolus can be obtained through a posterolateral approach to the fibula.

**DIRECT LATERAL APPROACH TO THE FIBULA**

**Exposure**
- The incision is kept just off the posterior border of the fibula but may be adjusted slightly based on soft tissue considerations (TECH FIG 1A).
- Deeper tissues are incised in line with the skin incision (TECH FIG 1B).
- Care must be taken proximally in the wound to avoid injury to the superficial peroneal nerve, which crosses...
Chapter 19  ORIF OF THE ANKLE 691

TECHNIQUES

the field about 7 cm proximal to the distal tip of the fibula (TECH FIG 1C).

■ Next, the peroneal fascia is divided and the peroneal tendons and musculature are retracted posteriorly.
■ With gentle elevation of the peristeam about the fracture site, the fibula should be exposed.
■ Care should be taken to avoid excessive stripping of fracture fragments as well as iatrogenic disruption of the syndesmotic ligaments as they insert anteriorly on the fibula.

Lateral Plating

■ Following exposure of the fracture, the first step involves cleaning the fracture site (TECH FIG 2A), followed by fracture reduction.
■ Usually reduction is afforded by a small “lion jaw” clamp or pointed reduction forceps.
■ If reduction is difficult, manual traction with pronation and external rotation will afford fracture alignment in supination–external rotation patterns.
■ Care should be taken to avoid placing clamps over fracture spikes to prevent inadvertent comminution (TECH FIG 2B).

■ If the clamps make it difficult to place a lag screw, provisional Kirschner wires may be placed across the fracture and the clamps removed (TECH FIG 2C).
■ At this point, if a lateral plate is chosen, the lag screw is placed in the anterior-to-posterior direction, perpendicular to the fracture.
■ If a posterior plate (antiglide) is chosen, the lag screw is placed through the plate in a posterior-to-anterior direction.
■ In either case, the near cortex is overdrilled with a 3.5-mm drill bit, followed by drilling of the far cortex with a 2.5-mm drill bit (TECH FIG 2D).
■ The length of the screw is measured and a self-tapping 3.5-mm screw is placed across the fracture in the screw track.
■ Next a one-third tubular plate is placed directly lateral on the fibula (neutralization).
■ The proximal screw holes are filled with bicortical 3.5-mm screws after drilling with the 2.5-mm drill bit (TECH FIG 2E).
■ Distally, unicortical cancellous screws are placed, with care not to penetrate the distal tibia–fibula joint (TECH FIG 2F).
■ The wound is closed (TECH FIG 2G).

Exposure

■ The medial malleolus is approached via a gently curved anteromedial incision (TECH FIG 3A).
■ An incision is made parallel to the saphenous vein that is either concave anterior or concave posterior to allow visualization of the anteromedial joint.
TECH FIG 3 • A. For a medial-side injury, the skin incision is curved about the medial malleolus. B. Fracture site is exposed and cleaned of hematoma and the talar dome is inspected for signs of chondral injury.

- After dissection of the skin, the subcutaneous tissues should be carefully dissected to prevent injury to the saphenous vein and nerve.
- With the dissection carried down sharply to the bone, the periosteum is elevated for 1 mm proximally and distally.
- The fracture should be booked open to allow visual inspection of the talar dome for chondral injury.
- The joint and medial gutter should be irrigated through the fracture for any loose hematoma or debris that may impede reduction (TECH FIG 3B).

Operative Stabilization
- Following exposure, the medial malleolar fragment (usually one large piece) can be reduced with the aid of a dental tool or small pointed reduction clamp (TECH FIG 4A).
- The fragment can be provisionally stabilized with small-diameter Kirschner wires placed in parallel (TECH FIG 4B).
- After radiographic documentation of the reduction and wire placement, cannulated screws of appropriate length may be placed over the wires after drilling of the outer cortices with a cannulated drill. Alternatively, noncannulated screws may be used independent of the provisional stabilization.
- Usually, a 4.0-mm partially threaded cancellous screw can be placed. If the fragment is small, however, 3.5- or 3.0-mm cannulated screws are now available.
- More recent studies have advocated for the use of two bicortical 2.7-mm screws placed in lag mode.
- Two screws are recommended for rotational control. If the fragment is too small, however, one screw may suffice owing to the inherent stability of the undulating fracture line.
- Countersinking the screw heads medially may help to alleviate painful prominent hardware.
- Comminuted fractures that are not amenable to screw fixation may benefit from a small buttress plate or a “suture tension band” technique using the deltoid ligament for fixation.
- The suture or wire tension band is anchored about a more proximal screw placed parallel to the articular surface.

POSTEROLATERAL APPROACH TO THE TIBIA
- Direct access to the posterior malleolus fracture (TECH FIG 5A) can be obtained through the posterolateral approach to the fibula (TECH FIG 5B).
- The interval between the Achilles and the peroneal muscle is developed (TECH FIG 5C).
- The flexor hallucis longus is taken off the fibula down to the interosseous membrane, and then the rest of the deep posterior compartment is taken off the posterior tibia (TECH FIG 5D).
POSTERIOR MALLEOLUS FIXATION

- If an adequate reduction can be achieved via closed, indirect reduction, the fracture can be stabilized with cannulated lag screws placed in the anterior-to-posterior direction.
- If an open approach is used for reduction, screws placed posterior to anterior may be placed across the fracture site.

- If the fracture fragment is of sufficient size, an antiglide plate (one-third tubular) may be placed with undercontouring of the plate to provide a satisfactory buttress effect (TECH FIG 6).

TECH FIG 5 • Direct posterior plating is well suited for fractures involving large portions of the posterior malleolus. A. Postreduction lateral radiograph showing a posterior malleolus fracture involving more than one third of the articular surface. B. Patient in prone position, incision between Achilles and posterior fibula border. C. Access is via the interval between the flexor hallucis longus and the peroneal muscle belly. D. Posterior malleolar fragment following fibular plating.

TECH FIG 6 • Postoperative AP and lateral radiographs demonstrating posterior plating of the tibia to buttress the posterior malleolar fracture fragment.
POSTERIOR PLATING OF THE FIBULA

- In this case, the surgical approach is similar to the lateral plating technique.
- When application of a posterior or antiglide plate is chosen, placement of a lag screw is optional.
- My preferred method is to apply the plate along the flat posterior surface of the bone, using it as a reduction aid with a bone reduction clamp (TECH FIG 7A).
- I prefer to place a posterior-to-anterior–directed lag screw through the plate.
- Because of the biomechanical properties of this plate construct, this lag screw is optional.
- Next, at least two or three bicortical screws are placed in the plate. A bicortical screw placed posterior to anterior in the distal screw is optional.
- If a posterior plate is applied, the proximal screws are placed bicortically from posterior to anterior, both proximal and distal to the fracture. This is an advantage in osteoporotic bone (TECH FIG 7B).

SYNDESMOSIS FIXATION

- After stabilization of the medial and lateral sides of the ankle, syndesmotic integrity should be assessed.
- The Cotton test involves providing a lateral force on the fibula with a bone hook or bone clamp (TECH FIG 8A).
- Lateral displacement that allows more than a few millimeters of tibiofibular widening is considered pathologic and an indication for syndesmotic fixation.
- The lateral radiograph should be scrutinized to assess the relationship of the fibula to the articular surface of the ankle joint. In general, on a true lateral view of the ankle, the tip of the fibula should be anterior to the posterior border of the diaphyseal tibia, but comparisons to the contralateral ankle can be assessed.
- With a bolster behind the ankle, a large tentaculum clamp is placed across the tibiofibular joint, with one tine on the distal tibia and the other on the fibula (TECH FIG 8B).
- Reduction is confirmed on the AP, mortise, and lateral radiographic views.
- While dorsiflexion of the talus has been recommended in the past to prevent overtightening of the syndesmosis, more recent studies have shown that it is virtually impossible to overtighten an anatomically reduced mortise.
- Fixation choices range from one or two screws, with three or four cortices drilled and 3.5-mm or 4.5-mm screw diameters used. Although the size and number of screws remain controversial, some parameters are agreed on.
- The screw should be placed 1.5 to 2 cm proximal and parallel to the joint.
- The screw should not be placed in lag mode.
- If a lateral plate is used, the screw is placed through one of the distal holes.
- If a posterior plate is used, the syndesmosis screw will likely be placed outside the plate on the lateral cortex.
### POSTOPERATIVE CARE
- All ankles should be splinted in the neutral position and elevated for at least 24 hours postoperatively.
- We remove the splint at 10 to 14 days and remove the sutures.
- Patients are then placed into a removable functional brace that allows them to begin early active-assisted and passive range of ankle motion.
- Patients are also allowed to begin isometric strengthening exercises.
- All patients are kept non-weight bearing for at least 6 weeks.
- At 6 weeks patients are progressed to weight bearing as tolerated based on radiographic criteria.
- Weight bearing can be delayed for slow healing and presence of a syndesmotic screw. In general we do not alter the weight-bearing status because of syndesmotic injury or routinely remove the syndesmosis screw, but we advise patients of the possibility of screw breakage following weight bearing.
- Patients are restricted from operating an automobile for 9 weeks following right-sided ankle fracture.

### OUTCOMES
- One year after ankle fracture surgery, patients generally do well, with most experiencing little or mild pain and few restrictions in functional activities. They have significant improvement in function compared with 6 months after surgery.
- Younger age, male sex, absence of diabetes, and a lower American Society of Anesthesia class are predictive of functional recovery at 1 year following ankle fracture surgery.
- It is important to counsel patients and their families on the expected outcome after injury with regard to functional recovery.
- Looking specifically at elderly patients (older than 60 years), functional outcomes steadily improved over 1 year of follow-up, albeit at a slower rate than in the younger patients.
- Our results suggest that operative fixation of unstable ankle fractures in the elderly can provide a reasonable functional result at the 1-year follow-up.

COMPICATIONS

- Minor complications include epidermolysis (FIG 5A), superficial infection, and peroneal tendinitis with painful hardware.
- Major problems include nonunion (FIG 5B), hardware failure, deep infection, and compartment syndrome.

REFERENCES

DEFINITION
- Fractures of the talus are severe injuries affecting ankle and hindfoot joint function.
- Displaced fractures of the talus are a surgical challenge to orthopedic surgeons. The injuries are infrequent and the fracture anatomy is partially concealed by adjacent osseous structures.
- Open reduction and internal fixation is generally mandatory to restore talar anatomy precisely.
- Outcomes of talus fractures correlate with injury severity. These results include ankle and subtalar joint stiffness, post-traumatic arthritis, and osteonecrosis of the talus.

ANATOMY
- Two anatomic factors play significant roles in the outcome of talus fractures.
  - Sixty percent of the bone is covered by articular cartilage, significantly limiting extraosseous perfusion to the bone.
  - Disruption of circulation to the talus correlates with open or comminuted talus fractures, leading to an increased risk of avascular necrosis. The blood supply to the talar body enters through the inferior talar neck via the artery of the tarsal canal. This key vessel originates from the posterior tibial artery. Secondary blood supply to the body is derived from the deltoid branch of the posterior tibial artery, entering the talar body along its medial surface. Circulation to the neck, head, and lateral body is supplied via the dorsalis pedis, tarsal sinus, and lateral tarsal sinus arteries. This last artery is an anastomosis between the peroneal and dorsalis pedis arteries.
- The talus has seven articulations.
  - Three main surfaces articulate with the plafond and lateral malleolus, while three surfaces articulate with the calcaneus.
  - The final articulation of the talar head with the tarsal navicular represents an important articulation for midfoot motion.
- Predictable stiffness with range of motion and posttraumatic arthritic changes is experienced with severe fractures of the talus.

PATHOGENESIS
- Fractures of the talus present in varying patterns depending on the mechanism of injury.
- Fractures of the talar head are intra-articular and the result of axial load to the talonavicular joint with the foot positioned in plantarflexion.
  - These fractures constitute up to 10% of all fractures of the talus.
  - They are uncommon but must be looked for in the event of an isolated subtalar dislocation.
- Talar neck fractures occur in the frontal plane and result from dorsiflexion of the foot against the anterior lip of the distal tibia. The fracture begins transversely along the medial talar neck due to an associated supination force to the hindfoot.
- The fracture line extends laterally. The fracture may be extra-articular, intra-articular, or a combination of both. With increased energy, the hindfoot supination force generates a fracture of the medial malleolus of the ankle.
  - After completion of the neck fracture, continued hyper-dorsiflexion and axial load to the body of the talus may force dislocation of the talar body posteriorly, disrupting significant extraosseous circulation.
- Fractures of the body of the talus involve up to 23% of talus fractures. The mechanism of injury is the same for body fractures as for fractures of the talar neck.
- Fracture patterns of the body of the talus include coronal, sagittal, horizontal shear, and crush fractures of the weight-bearing surface.
- Process fractures of the talar body are described by anatomic location.
  - Lateral and posterior process fractures are sustained by inversion and eversion mechanisms of the ankle, respectively. These fractures are often missed on plain film radiographs of the ankle and diagnosed as ankle sprains.
  - Hawkins classified lateral process fractures into avulsion, isolated, and comminuted types.
  - Posteromedial and posterolateral process fractures lie to each side of the flexor hallucis longus tendon. These are commonly intra-articular fractures of the inferior surface of the posterior talus.

NATURAL HISTORY
- The postoperative prognosis for any displaced talus fracture should be guarded because of significant postinjury potential for complication.
- Fractures of the head of the talus are commonly nondisplaced because of powerful capsular and talonavicular ligamentous attachments.
- Displaced fractures of the talar head have a 10% incidence of osteonecrosis and can lead to secondary posttraumatic arthrosis.
- Fractures of the neck of the talus are defined as fractures anterior to the lateral process of the talus. Hawkins’ work on vertical fractures of the neck of the talus helped clarify injury of vascular perfusion to the bone by delineating three types of fractures of the neck of the talus.
  - The type I fracture is nondisplaced. Disruption of blood flow is limited to the anterolateral region of the bone. I recommend a computed tomography (CT) scan to confirm no displacement of the fracture before diagnosing a type I fracture. Historically, Hawkins reported a 13% incidence of osteonecrosis in type I injuries (FIG 1A).
  - In the type II talar neck fracture there is displacement of the talar dome fragment, which is routinely posterior, often depicting clear subluxation of the talar body. Blood flow to the medial body and head is preserved. The type II talar neck fracture has a 20% to 50% risk of avascular necrosis (FIG 1B).
In the type III injury, the transverse fracture of the talar neck is associated with dislocation of the talar body. The incidence of osteonecrosis of the talar body is 50% to 100%. All major perfusion to the body of the talus is damaged (FIG 1C).

A type IV injury of the talar neck has been documented; it is a type III fracture-dislocation with associated talonavicular dislocation. All extrasosseous blood flow to the talus is considered disrupted. The value of the Hawkins classification is that it allows the orthopedic surgeon to predict what to expect with a specific talar neck injury. Open reduction and rigid internal fixation is the recommended treatment (FIG 1D).

Talar body fractures are defined as fractures extending into or posterior to the lateral process.

PATIENT HISTORY AND PHYSICAL FINDINGS

Fractures of the talus are commonly associated with vehicular trauma and falls.

The relationship of severe lower extremity trauma and airbags is well known. After airbag deployment, the torso and lower extremities are directed toward the floor panel of the car.

I believe that the incidence of high-energy hindfoot trauma will increase over time. Globally, transport related injuries remain the leading cause of disability from injury. By 2020, traffic injuries will increase from a current 9th position to 3rd disability-adjusted life years lost.

The history and the clinical status of the talar injury must be carefully recorded because the injury severity is likely to correlate with the long-term patient outcome.

On the initial examination the physician should note pain, motion, crepitus, deformity, soft tissue swelling, open fractures, and associated fractures of adjacent bones to the foot and ankle and should perform a complete neurovascular evaluation of the extremity.

Detailed documentation of the talus fracture pattern and local soft tissue injury is paramount.

Soft tissue local pressure phenomenon, commonly found anterolaterally in closed type III fractures of the talar neck, may precipitate full-thickness pressure necrosis of the skin if not decompressed early.

Severe swelling of the ankle is common in the acute fracture of the talus and may progress to fracture blister formation, precluding safe execution of operative incisions.

The physician should examine the skin for swelling, ecchymosis, fracture blisters, and deformity; these are signs of a closed fracture.

A closed injury with mild or moderate swelling (bony landmarks palpable) indicates talar neck type I and II fractures and process fractures.

A closed injury with severe swelling indicates talar neck type III and IV fractures and body fractures.

Open fractures will be apparent by the transverse, medial, or supramalleolar traumatic laceration of the ankle. Lateral, posterior, and plantar wounds are uncommon.

The physician should perform vascular, neurosensory, and myotendinous examinations of the foot and ankle.

IMAGING AND OTHER DIAGNOSTIC STUDIES

Three plain radiographic views are necessary to radiographically evaluate talus fractures: anteroposterior (AP), mortise (15-degree internal rotation view), and lateral images of the ankle.

The AP and mortise views of the ankle demonstrate alignment of the talar body in the ankle mortise. The lateral view depicts the sagittal outline of the talus.

The Canale view is used to assess varus or valgus malalignment of the talar neck, particularly with Hawkins type I and II injuries. The knee must be flexed and the foot in equinus and everted, with the x-ray tube directed 15 degrees caudad (FIG 2A).
Because of the high-energy nature of fractures of the talus, AP and oblique views of the foot should be a standard addition to the three-view plain film ankle protocol so as not to miss associated midfoot and forefoot injuries (FIG 2B).

Computed tomography (CT) provides important additional information to the three-view plain film series of the ankle. Thirty-degree coronal and paraxial CT imaging is important to confirm Hawkins type I fractures of the talar neck and plan treatment of talar body fractures with extension posterior to the lateral process. Reconstructions of both sagittal and coronal CT studies provide valuable information about incremental pathoanatomy of the entire talus, medial to lateral and anterior to posterior, respectively. In addition, confirmation of a process fracture that is not clearly viewed by plain film is easily diagnosed by CT (FIG 2C).

DIFFERENTIAL DIAGNOSIS

- Process fracture of the talus
- Lateral process fracture
- Medial process fracture
- Head of talus fracture
- Neck of talus fracture
- Body of talus fracture
- Neck and body of talus fracture
- Fracture-dislocation of talus
  - Involving body
  - Involving neck and body
- Extruded talus

(Any of these injuries to the talus may be open fractures, affecting management.)

NONOPERATIVE MANAGEMENT

- Fractures of the talus include a spectrum of injury patterns ranging from isolated regions of the talus (e.g., lateral process) to severely comminuted talus fractures involving all parts of bone, making nonoperative management inappropriate.
- High-energy injury mechanisms that cause talus fractures precipitate fracture displacement and joint surface incongruity.
- Medial and lateral process fractures, minimally displaced (less than 2 mm) and involving less than 1 cm of bone, are commonly managed nonoperatively.
- These injuries are treated acutely in well-padded, compressive dressings with posterior splints and non-weight bearing. Swelling and immediate pain in the ankle improve significantly by 7 to 10 days. The patient is subsequently converted to a short-leg non-weight-bearing cast for 6 weeks, followed by progressive range of ankle and subtalar motion and return to weight bearing in a removable fracture-boot.
- If the process fracture is severely comminuted, precluding surgical reconstruction, the same initial and definitive nonoperative management is employed.
- Isolated fractures of the head of the talus without dislocation and without displacement are largely stable fractures. These injuries require plain radiographic evaluation of both the ipsilateral foot and ankle to confirm the isolated nature of the injury. I recommend CT scanning (axial and transverse views of foot and ankle) of this injury to rule out associated midfoot pathology.
- Acutely, an isolated, nondisplaced talar head fracture is splinted for 7 to 10 days with subsequent short-leg casting in neutral plantarflexion with non-weight bearing for 4 weeks. Intermittent daily ankle and subtalar motion with Achilles tendon stretching should follow with application of a removable fracture boot. The patient remains non-weight bearing until 6 to 8 weeks after injury. Next, progressive weight bearing, range of motion, stretching, and strengthening of the entire lower extremity are recommended.
- The Hawkins type I fracture of the neck of the talus is a nondisplaced talar neck fracture. The talus remains anatomically positioned in the ankle and subtalar joint with minimal potential for disruption of perfusion to the bone.
- A subgroup of these injuries may present with displacement of the talar neck on initial injury plain radiographs. After closed manipulation of the fracture in plantarflexion, the talar neck fracture may reduce. A true Hawkins type I talar neck fracture will not displace even with gentle dorsiflexion. The type I fracture strongly warrants a CT scan,
with sagittal reconstruction, to confirm anatomic alignment of the talar neck.

- If there is displacement of the neck fracture, the injury must be reclassified as a type II, which requires surgical treatment to obtain, and maintain, the reduction.
- Truly nondisplaced fractures of neck of the talus can be treated nonoperatively in a short-leg non-weight-bearing cast for 6 to 8 weeks. Close follow-up is recommended to watch for any displacement of the neck fracture. At 6 to 8 weeks after the injury, progressive weight bearing, range of motion, stretching, and strengthening are initiated.
- Injury forces precipitating fractures of the dome of the talus are universally severe, causing articular displacement, and are an indication for surgery. Open fractures of the talus, even with no displacement, are best managed with rigid surgical stabilization to allow for wound care and early motion.

**SURGICAL MANAGEMENT**

- The timing of operative management of talus fractures has been an area of controversy, specifically whether the displaced talus fracture is an orthopedic emergency.
- One recent study indicates that orthopedic trauma surgeons do not believe a displaced fracture of the neck of the talus is an orthopedic emergency.
- However, it is important to differentiate the potential of vascular injury to the talar body from soft tissue and neurovascular compromise of the foot because of injury to the talus. In particular, fracture-dislocation of the body of the talus is associated with compromised blood flow to the bone, the threat of pressure phenomenon to the skin, and possible tibial nerve dysfunction.
- The acute severity of soft tissue swelling or the impact of an open hindfoot wound may preclude safe, immediate reconstruction of the talus fracture after reduction of the dislocation.
- Foot and ankle external fixation is a suitable treatment option, with staged definitive fixation applied accordingly.
- Any open talus fracture must be treated as an orthopedic emergency.
- Preoperative antibiotics may be selected on the basis of wound contamination. These include a cephalosporin and possibly gentamicin. Penicillin is added if gross or farm contamination is present. All patients should receive a tetanus toxoid booster.
- The patient is taken to the operating room and after soft tissue debridement the wound receives at least 3 to 9 L of normal saline using pulsed lavage.
- At this time, in addition to partial or complete fixation of the talus fracture, provisional foot and ankle external fixation may be used to provide soft tissue and osseous stabilization before delayed closure.
- Regarding general guidelines for fractures of the body, neck, and head of talus fractures, surgical management is indicated with fracture displacement, malalignment, subluxation, dislocation, or instability.
- Recent studies indicate that displacement or malalignment will have a negative impact on foot function. Two millimeters of fracture displacement has been shown to affect subtalar joint mechanics.
- There is less agreement regarding surgical indications for process fractures of the talus. Acute, displaced fractures with large fragments showing extension into the subtalar joint by CT imaging are best treated with open reduction and internal fixation.
- A displaced fracture of the neck of the talus is one of the most common indications for surgery on the talus. The fracture is known to start, in the coronal plane, along the medial neck and extend laterally until completion.
- There are two common types of neck fractures: an extra-articular pattern and an intra-articular type that extends into the subtalar joint.
- The displaced extra-articular vertical neck fracture is routinely amenable to closed reduction by applying dorsal-to-plantar pressure on the head of the talus associated with longitudinal traction and plantarflexion of the forefoot. Immediate reduction of this fracture diminishes concerns for soft tissue, neurovascular, and osseous compromise.
- The intra-articular pattern is less likely to cooperate with closed manipulation owing to the obliquity of the fracture as it extends posterior into the subtalar joint. This fracture pattern is more deserving of immediate or early surgery.
- For patients with severe open fractures of the talus, or closed injuries in which soft tissue compromise precludes immediate open management, temporizing external fixation may be effective.
- The goals of temporary external fixation are to maintain the length of the talus for reconstruction, facilitate soft tissue management, and restore general alignment. External fixation is rarely definitive management for talus fractures.
- Displaced, open or closed, fractures benefit most from rigid internal fixation for bone healing and early motion. However, a recent report evaluating results of the extruded talus identified definitive external fixation as an option to manage the purely dislocated talus. This is an excellent treatment option to stabilize the ankle and subtalar and talonavicular articulations of the talus.

**Preoperative Planning**

- Operative planning for talus fractures requires evaluation of imaging studies to clearly understand the relationships of all major fracture fragments.
- A preoperative CT scan of the fracture is standard when confronted with a comminuted talar neck or body fracture. The surgeon must become familiar with the morphology of the bone and its many contours to facilitate reconstruction.
- Intraoperative visibility and access to talar fragments are routinely challenging, but these variables can be largely facilitated by correct patient positioning, surgical approaches, adequate operating room lighting (headlamp), attention to reduction techniques, and implants selected. All play a key role in preoperative planning.
- The principles of open treatment are restoring articular congruity, maximizing the revascularization potential of the bone, and allowing early motion of the ankle and subtalar joints.
- The use of a radiolucent table and a headlamp promotes optimal visualization.
- A tray of fine-tipped, sharp and strong bone elevators, dental probes, Freer elevators, small bone clamps, mini/small lamina spreaders, and small distractors or external fixation equipment is routinely needed not only for talus fracture fixation but also all fine articular fracture reconstructions.
Small interfragmentary (3.5 mm) cortical screw fixation and mini-fragment (2.7 or 2.0 mm) screw/plate instrumentation is commonly needed for talus fracture fixation.
- An extra-long mini-screw (2.7 or 2.0 mm) inventory is recommended, with screws up to 60 mm long.
- The use of mini-implants is particularly helpful when reconstructing comminuted fractures.
- Contemporary mini-fragment systems are predominantly stainless steel.
- Some authors have suggested using titanium implants to allow use of magnetic resonance imaging to assess osteonecrosis.
- Osteochondral fragments too small for mini-fragment fixation can be fixed with bioabsorbable pegs or headless articular screws.

Positioning
- Displaced fractures of the head, neck, body, and lateral process of the talus are best reconstructed with the patient in the supine position.
- Supine positioning allows medial, anterolateral, and direct lateral incisions to be performed with ease (FIG 3A,B).
- Intraoperative fluoroscopy is conveniently performed with the patient in this universal position.
- The patient should have an adequate bump placed preoperatively under the ipsilateral gluteal region to avoid external rotation of the ankle.
- Fractures of the posterior body of the talus are performed through posteromedial or posterolateral surgical approaches. These approaches are achieved most efficiently with the patient in the prone position (FIG 3C).
- The prone or lateral recumbent position is effective for occasional posterior-to-anterior fixation associated with minimal or no displacement of the fracture.
- A radiolucent table without attachments at the foot allows for all required radiographic views.

Approach

Medial and Anterolateral Approach
- Anatomic reduction of displaced head, neck, and body fractures requires visualization of both medial and lateral surfaces of the talus. A medial and anterolateral (two-incision) approach effectively prevents a malreduction of the articular surfaces and neck.
- A surgeon’s initial impression of the dual-incision approach to talus fractures may be perceived to disregard the biology of the bone and its limited extraosseous blood supply. With attention to detail, neither the plantar nor the direct dorsal blood supply to the talus is violated.
- Landmarks for the medial incision are the dorsomedial tip of the medial malleolus extended, in line with the axis of the foot to the tarsal navicular (FIG 4A).
- This incision is 5 mm dorsal to the axis of the posterior tibial tendon.
- Its extension continues just distal to the navicular tuberosity, allowing exposure of the medial surface of the talar head, neck, and distal body.
- The approach may be lengthened in both directions to improve visibility.
- The anterolateral incision is parallel and 5 to 6 cm lateral to the medial approach (FIG 4B).
Part 2 PELVIS AND LOWER EXTREMITY TRAUMA • Section IV FOOT AND ANkle

This incision should begin just medial or in line with the syndesmosis of the ankle.

The lateral neck of the talus is difficult to access and reconstruct if the incision is made too lateral.

If comminution of the lateral process is to be addressed, the incision can be shifted slightly lateral.

After completing the skin incision, the surgeon must beware of the lateral branch of the superficial peroneal nerve when incising deep to the subcutaneous tissues.

The lateral retinaculum must be sharply incised, and the extensor digitorum tendons are retracted medially, exposing the extensor digitorum brevis muscle.

The muscle belly is reflected distally off its proximal origin, allowing easy access to the lateral capsule of the talus.

The lateral capsulotomy is made in line with the axis of the neck of the talus.

Anatomic reduction of complex talus fractures is achieved by working from side to side through both incisions.

Transmalleolar Approach

An important modification of the medial approach to the talus is the medial malleolar osteotomy. In displaced body or complex talar neck fractures, the procedure may be greatly facilitated by this increased exposure.

I prefer to continue the medial incision longitudinally, directly in line with the axis of the medial malleolus, extending just proximal to the supramalleolar region (FIG 5A).

After exposing the malleolus, without violating the periosseum, the distal tip of the anterior and posterior colliculus of the medial malleolus must be predrilled (FIG 5B) and tapped retrograde for two parallel, 3.5-mm interfragmentary cortical or 4.0-mm partially threaded cancellous screws.

An oblique osteotomy directed toward the shoulder of the medial ankle mortise is performed using a very thin oscillating saw blade.

This osteotomy is incomplete, advancing only to the level of the medial subchondral bone.

The osteotomy is completed by gentle levering of a thin wide osteotome on the inner cortex (FIG 5C).

At this time, an anterior and partial posterior capsulotomy of the medial malleolus is needed to allow inferior mobilization of the malleolus. The deltoid vessels perfusing the medial body of the talus are protected with gentle retraction.

Patients requiring this transmalleolar approach will routinely benefit from the associated anterolateral incision for optimal visualization of the proximal neck and body of the talus during reconstruction.

Posterior Approach

An isolated posterior body fracture of the talus or displaced Hawkins type III fracture may require a posteromedial or posterolateral approach for fracture reduction and management.

The incision is longitudinal, beginning at the midpoint of the calcaneus and extending a fingerbreadth medial or lateral to the Achilles tendon for approximately 6 to 8 cm (FIG 6).

When making the incision through the deep posterior compartment fascia, the surgeon must take care to identify and gently retract the medial neurovascular structures.

The posterior tibial nerve and artery may be tethered over a posteriorly dislocated talar body fragment in a Hawkins type III fracture-dislocation, warranting extreme caution during the approach.

After safely retracting the nerve and artery, the flexor hallucis longus (FHL) tendon represents a landmark directly posterior to the body of the talus.

The FHL tendon is then retracted laterally to begin the reconstruction.

Lateral Approach

Lateral process fractures of the talus are easily accessed using a direct lateral approach.

A longitudinal 6- to 8-cm direct lateral incision is started 3 cm proximal to the distal tip of the lateral malleolus of the fibula, extending anteriorly in a curvilinear incision, in line with the axis of the foot.

The lateral retinaculum and subtalar capsule are incised longitudinally, exposing the lateral process fracture (FIG 7).
FIG 5 • A. Transectal medial malleolar osteotomy. B. Predrilling of medial malleolus. C. Malleolar osteotomy complete.

FIG 6 • A. Posteromedial incision. B. Flexor hallucis longus concealing posterior talus. C. Hemarthrosis of posterior capsule.
OPEN REDUCTION AND INTERNAL FIXATION OF THE NECK OF THE TALUS

Reduction
- After completion of the medial approach, limited sharp dissection is performed only along the medial neck and head to remove extraosseous soft tissue attachments and expose the talar body, neck, and head and the talonavicular joint.
- The medial fracture line is commonly found to have comminution that affects understanding of the true length and alignment of the medial column of the bone.
  - Inserting a mini-lamina spreader to gently disimpact the medial talar neck fracture allows restoration of length and alignment of the medial and dorsal surface of the neck.
  - Anatomic alignment is achieved using the dental probe and small elevators as reduction tools.
- If the talar neck fracture is intra-articular with extension into the subtalar joint, the body fragment routinely assumes a flexed, malrotated position.
  - To derotate the talar body’s flexed position, the surgeon should firmly secure a percutaneous 4.0-mm external fixation half-pin into the body fragment through a posterolateral stab incision, acting as a joystick.

Trial Fixation
- Once the talar neck is reduced, the next step is to advance a single smooth Kirschner wire retrograde through the talar head, directed across the fracture into the posterior body, to hold the position of the medial talar neck fracture.
  - If no bony reduction keys are visible along the medial talar neck, due to comminution, the mini-lamina spreader is inserted in the fracture medially while the surgeon patiently reduces the medial talar neck alignment.
  - Talar neck fluoroscopy is necessary to evaluate translation and alignment of the fracture. This important step establishes the true length and alignment of the medial talar neck.
  - Again, a retrograde smooth or threaded wire is advanced across the fracture.

- The surgeon then exposes the lateral neck of the talus.
  - The extra-articular fracture line reveals the lateral shoulder of the talus.
  - Comminution is rare; the fractures are simple, discrete patterns that reduce relatively easily by rotating around the medial Kirschner wire.
  - After reduction, a retrograde Kirschner wire is advanced through the lateral talar head and across the fracture, provisionally fixing the lateral side of the talus fracture.
  - Intraoperative fluoroscopy is performed to confirm the precise reduction of the fracture.
  - Close attention is paid to the Canale image of the talar neck to be sure there is no malalignment of the neck fragment.

Screw Fixation
- Definitive fixation of the medial talar neck fracture is achieved by gently subluxing the medial talonavicular joint to expose the articular surface of the talar head (TECH FIG 1).
  - A countersunk interfragmentary 3.5-mm screw is advanced to the posterior body of the talus.
  - Laterally, very dense cortical bone along the proximal neck presents an excellent extra-articular location for advancing a second interfragmentary screw.
  - Fracture patterns of the talus make it difficult to insert parallel interfragmentary screws.
  - The medial screw is easily directed posterolaterally and the lateral screw posteromedially.
  - This pattern of fixation has never been found to affect healing.

Plate Fixation
- Talar neck fractures that are not amenable to interfragmentary screws because of comminution perform well with mini-plate fixation.
  - Four- or five-hole 2.0-mm mini-plates are easily contoured and applied along either the medial or lateral neck surfaces for fixation in these cases (TECH FIG 2).
  - Plate fixation is especially helpful in cases with lateral comminution, or when the lateral shoulder is proximal to the fracture.
Chapter 20  ORIF OF THE TALUS 705

A
B
C

TECH FIG 1 • A. Bone model highlighting medial intra-articular, lateral extra-articular, and posterior screw fixation. B. Hawkins type II fracture. C. Postoperative fixation.

■ Talar neck fractures with associated posterior dislocation of the body fragment (Hawkins type III) present an increased challenge to the surgeon.
■ Fracture-dislocation of the body and talar head fragments (Hawkins type IV) is a severe pantalar injury, but reduction of the talonavicular joint is easily achieved through medial and anterolateral approaches.

OPEN REDUCTION AND INTERNAL FIXATION OF THE NECK OF THE TALUS WITH A DISLOCATED TALAR BODY

■ Reduction of the body fragment is an immediate goal with either injury type to diminish stretch on neurovascular structures and decompress local pressure phenomenon of the skin envelope.
■ The body commonly dislocates posteromedially because of the retained tether from the deep deltoid ligament. However, the body may dislocate directly posteriorly or posterolaterally.

■ A open Hawkins type III fracture-dislocation allows the surgeon access to the body fragment through the common transverse medial traumatic wound.
■ A closed Hawkins III injury may warrant a posteromedial or posterolateral incision to access the body fragment if it cannot be retrieved through the medial approach.
■ An associated medial or lateral malleolar fracture of the ankle helps reduction of the talar body dislocation immensely, particularly with disruption of the syndesmotic ligament.
■ Reduction of the dislocated body fragment may be attempted in the emergency room using radiographic information and conscious sedation.
■ A well-controlled, single attempt at closed reduction is reasonable.
■ The hindfoot is positioned in equinus and the subtalar joint is distracted by gripping the heel and applying traction.
Next, the dislocated talar body fragment is pushed anteriorly.

The main tether, if one exists, to the dislocated talar body fragment is the deep deltoid ligament medially. If intact, the deep deltoid ligament, which is short and nonelastic, allows for little motion, minimizing the yield of successful closed reduction.

If the closed reduction is unsuccessful, manipulation and reduction under general anesthesia is recommended immediately in the operating room.

**Percutaneous Reduction**

- A percutaneous reduction can be an effective and quick next step, particularly if the dislocated talar body is a single fragment.
- With the patient in the supine position, a large, firm sterile bump must be positioned under the calf of the patient.
- A 4-mm external fixation half-pin is advanced through the posterior tuberosity of the calcaneus, in line with the long axis of the bone, to the subchondral surface of the anterior process of the calcaneus.
- Next, a medial-to-lateral 4-mm half-pin is advanced across the dense subchondral distal tibia bicortically.

**Reduction of the Talar Dome Fragment**

- A final 4-mm half-pin is manually, and carefully, advanced deep into the body of the talus through a 1.5-cm longitudinal incision.
- The rationale of the pin placement should be clear.
- The long calcaneal pin has terrific mechanical advantage with traction to the torn posterior capsule of the ankle.
- The surgeon distracts the distal tibial and calcaneal pin while a surgical assistant attempts to reduce the talar body anteriorly using the half-pin as a joystick.

**OPEN REDUCTION AND INTERNAL FIXATION OF THE BODY OF THE TALUS**

- Reconstruction of talar body fractures is best performed using dual medial and anterolateral approaches with the addition of the medial malleolar osteotomy.
- Unless the fracture line is transverse and very anterior, allowing reasonable access by a standard dual approach, a transmalleolar approach is planned.
- Fracture patterns to the body of the talus occur in both sagittal and coronal planes. Regardless of the fracture plane, the principle is to work through the fenestration provided by the medial malleolar osteotomy, using fine-tipped dental probes, reducing the posterior portion of the body to the anterior body fragments.

- Small, smooth Kirschner wires are inserted from medial and lateral portals, provisionally fixing the body.
- Associated fractures of the neck of the talus are provisionally fixed after reduction of the body fracture.
- Interfragmentary, countersunk, mini-screws (2.7 or 2.0 mm) are sequentially inserted, fixing the body fragment.
- Headless screws can also be used for this fracture.
- Finally, countersunk, interfragmentary small fragment (3.5 mm) screws or mini-plate and screw constructs are used to fix the talar neck fracture (TECH FIG 3).
Displaced, intra-articular posterior talar body fractures present largely in the coronal plane (TECH FIG 4).

I prefer to position the patient prone, on a sterile bump, and access the fracture through the posteromedial approach.

Before inflation of a tourniquet, I recommend inserting medial, distal-third tibial and calcaneal external fixation half-pins. This will allow for application of a small femoral distractor, which aids in ankle and subtalar joint distraction.

A headlamp worn by the operating surgeon aids visualization in this approach.

OPEN REDUCTION AND INTERNAL FIXATION OF THE POSTERIOR BODY OF THE TALUS

- Narrow Hohmann retractors are gently applied medially and laterally within the ankle joint, retracting the posterior tibial nerve and artery and FHL tendon, respectively. This allows exposure of the posterior talar fragment.
  - The fracture is reduced using dental probes.
  - Smooth Kirschner wires are inserted, posterior to anterior, provisionally fixing the fracture.
  - The fracture is fixed either by interfragmentary, parallel screw fixation or a well-contoured mini-plate and interfragmentary screws.
  - The posterior mini-plate is contoured in a curvilinear fashion to securely buttress the posterior talus.
OPEN REDUCTION AND INTERNAL FIXATION OF THE LATERAL PROCESS OF THE TALUS

- Open reduction and internal fixation of fractures of the lateral process of the talus may be performed with the patient positioned either supine or direct lateral.
  - Intuitively, the patient should be supine if other surgery is to be performed on the foot and ankle.
  - After completing the lateral approach, the surgeon carefully evaluates the lateral process fracture (TECH FIG 5A,B).
  - I gently displace the fracture and assess the condition of the subtalar joint.
  - Small fragments are commonly devoid of soft tissue attachments. Only very small fragments should be removed.
  - Larger fragments, even those without soft tissue attachments, are needed to restore the structure of the lateral process in any closed fracture of the lateral process of the talus.
- Any anterior or posterior osteochondral fragments are reduced and provisionally fixed with small, smooth Kirschner wires.
- A Freer elevator is helpful to determine the anatomic subtalar joint line.
- Final reduction of the direct lateral fragments of the lateral process is provisionally fixed by Kirschner wires.
- Isolated lateral process fractures are best fixed by interfragmentary mini-screw fixation.
- Comminuted fractures should be buttressed by mini-screw and plate fixation to resist displacement against axial loads to the process (TECH FIG 5C,D).

OPEN REDUCTION AND INTERNAL FIXATION OF THE LATERAL PROCESS OF THE TALUS

- A talus devoid of soft tissue attachments should be immediately placed in a Bacitracin solution and transported to the operating room.
- After preparation and draping, the talus is placed in two or three Bacitracin and saline baths and gently scrubbed before reimplantation.
- A foot and ankle external fixator must be constructed (TECH FIG 6).
  - Initially, two 4-mm external fixation half-pins are inserted bicortically into the anterior distal third of the tibia.
  - A 4-mm half-pin is inserted bicortically into the base of the first and fifth metatarsals.
  - Finally, a 4-mm half-pin, or transfixion pin, is advanced from medial to lateral, bicortically, through the tuberosity of the calcaneus.
  - An external fixation rod connects the two metatarsal base pins, forming a midfoot unit. It is important to leave excess rod on each end of the midfoot unit for further tibial-rod attachment.
  - Next, an isolated, long external fixation rod is attached to the medial end of the midfoot unit and to the distal

EXTERNAL FIXATION

- A talus devoid of soft tissue attachments should be immediately placed in a Bacitracin solution and transported to the operating room.
- After preparation and draping, the talus is placed in two or three Bacitracin and saline baths and gently scrubbed before reimplantation.
- A foot and ankle external fixator must be constructed (TECH FIG 6).
  - Initially, two 4-mm external fixation half-pins are inserted bicortically into the anterior distal third of the tibia.
  - A 4-mm half-pin is inserted bicortically into the base of the first and fifth metatarsals.
  - Finally, a 4-mm half-pin, or transfixion pin, is advanced from medial to lateral, bicortically, through the tuberosity of the calcaneus.
  - An external fixation rod connects the two metatarsal base pins, forming a midfoot unit. It is important to leave excess rod on each end of the midfoot unit for further tibial-rod attachment.
  - Next, an isolated, long external fixation rod is attached to the medial end of the midfoot unit and to the distal
tibial half-pin, restoring neutral plantarflexion of the ankle.

- A second, long external fixation rod is attached to the lateral end of the midfoot rod and connected to the proximal tibial pin, controlling ankle varus and assisting dorsiflexion.

- Finally, external fixation rods are added, connecting the calcaneal pin to both the medial, midfoot rod and either tibial half-pin for increased frame rigidity and possibly to distract the subtalar joint.

**PEARLS AND PITFALLS**

<table>
<thead>
<tr>
<th>Avoid a medial approach to the neck of the talus plantar to the insertion of the posterior tibial tendon.</th>
<th>The tuberosity of the tarsal navicular is an important landmark identifying the plantar limit to the medial approach. Immediate swelling obscures palpation of this landmark.</th>
</tr>
</thead>
<tbody>
<tr>
<td>The neck of the talus is aligned eccentrically medial in the hindfoot.</td>
<td>The anterolateral surgical approach should not be lateral to the syndesmosis unless to address fixation of the lateral process of the talus or débridement of subtalar comminution.</td>
</tr>
<tr>
<td>A medial malleolar osteotomy performed distal to the shoulder of the medial ankle mortise gives poor visualization of the talar dome.</td>
<td>The osteotomy should be made at the level of the joint using a thin saw blade. The surgeon should protect the soft tissues posterior to the malleolus during the osteotomy.</td>
</tr>
<tr>
<td>Beware of fixing the neck of the talus in varus malalignment.</td>
<td>The surgeon should view the Canale image intraoperatively with C-arm fluoroscopy (flexed knee, everted foot in equinus and C-arm tube directed 15 degrees caudad).</td>
</tr>
<tr>
<td>Medial screw fixation of talar neck fractures, not countersunk in the talar head, commonly achieves poor fixation in the metaphyseal bone.</td>
<td>The surgeon should avoid medial percutaneous fixation of talar neck fractures.</td>
</tr>
<tr>
<td>Do not use posterior-to-anterior screw fixation, with the patient in the prone position, for a displaced talar neck fracture.</td>
<td>Posterior-to-anterior fixation does not allow reduction of a displaced fracture.</td>
</tr>
</tbody>
</table>
POSTOPERATIVE CARE

- The goal of operative and nonoperative treatment of talus fractures is to achieve bone union and restore hindfoot function.
- Return to preinjury status is commonly not achieved secondary to posttraumatic arthrosis and joint stiffness, but good functional outcomes are attained even in the most severe cases of talar neck and body fractures.
- Immediate postoperative treatment requires application of sterile ankle dressings and a well-padded, short-leg dressing with a posterior plaster splint.
- The ankle is positioned in neutral plantarflexion. Rigid internal fixation safely allows early postoperative ankle and subtalar motion.
- Before hospital discharge, the patient is taught to perform daily dressing changes and application of a foot and ankle compression Ace wrap to control swelling.
- The patient is to wear a removable short-leg fracture boot and remain absolutely non-weight bearing for 8 weeks.
- The fracture boot should be worn during the night for the initial 3 to 4 weeks after surgery to prevent an early Achilles tendon contracture.
- Active ankle and subtalar motion exercises are recommended.
- Immediate outpatient physical therapy after a talus injury routinely leads to excessive pain and ankle swelling.
- However, upper and contralateral lower extremity strengthening may be valuable during the initial, subacute, 6-week postinjury period.
- Partial avascular necrosis of the lateral dome of the talus is common. This may be seen because only the medial deep deltoid blood supply to the talus body remains intact after the injury.
- The Hawkins sign is an early subchondral radiolucent line indicating blood supply to the body of the talus. Its presence, seen on an AP radiograph at 6 to 8 weeks, indicates bone resorption, which is an active process requiring vascularity.
- Fortunately, patients with isolated regional osteonecrosis of the talar dome rarely experience late collapse.
- The lack of a Hawkins sign does not confirm osteonecrosis and may not be confirmed by plain radiographs until up to 3 months after the injury.
- There are no data to support extended periods of non-weight bearing in patients with partial avascular necrosis. Currently, the impact of weight bearing on the progression of osteonecrosis is unknown. Procedures designed to revascularize the talus, such as core decompression, are not recommended.
- Protected weight bearing with a patellar tendon-bearing brace to alleviate axial load to the hindfoot and refraining from repetitive-loading sports are reasonable early concerns to discuss with the patient.
- I recommend formal outpatient physical therapy starting at 6 weeks after surgery. The patient is non-weight bearing for 2 weeks, performing passive range of motion of the ankle and subtalar joints, isometrics of the leg, and possibly pool therapy.
- At 8 weeks, progressive weight bearing, strengthening, proprioception, and range-of-motion exercises ensue.
- Patients routinely display increased swelling of the injured extremity with weight bearing.
- Application of a 20- to 30-mm Hg compression stocking helps reduce swelling.
- By 3 months the patient should be weaned from the fracture boot and the transition made to an ankle brace applied within a shoe.
- Physical therapy can easily continue for up to 3 months with these injuries.
- The patient must be counseled on the importance of long-term exercise after the end of formal physical therapy.
- Nonoperative management of talus fractures requires cast immobilization for 6 weeks.
- After cast immobilization, the injury should be treated with a removable fracture boot and an outpatient physical therapy protocol.
- Progression to weight bearing is determined accordingly.
- Follow-up postoperative management requires a three-view plain radiographic ankle series.

OUTCOMES

- If the patient does not develop a complication of a talus fracture or its management, requiring secondary reconstructive surgery, the functional outcome should be considered a success.
- Recent data evaluating the surgical timing of talus fractures maintain that the time to surgery does not correlate with outcome. There is no association between delay of operative management and avascular necrosis. This makes a strong case for provisional external fixation of reduced talus fractures as immediate treatment, particularly if the condition of soft tissues does not allow early open management.
- Risk factors that lead to lower functional outcomes include comminution, a higher Hawkins classification, open fracture, and associated ipsilateral lower extremity injuries.
- Osteonecrosis of the talus, posttraumatic arthrosis, joint stiffness, and varus malalignment can have a negative impact on the outcome.
- The incidence of avascular necrosis of the talar body has been shown to increase with the severity of injury. The Hawkins sign has an accuracy of 75%. This sign is considered a good predictor of a vascularized talar dome; however, the absence of a Hawkins sign does not necessarily indicate progression of avascular necrosis.
- Recent studies evaluating talar neck fractures identify an overall 50% incidence of avascular necrosis, with evidence of collapse of the talar dome in 31% of the cases.
- Posttraumatic arthrosis secondary to these injuries is more common than avascular necrosis and most often presents in the subtalar joint.
- Ankle arthrosis does not occur as an isolated outcome; it is seen in association with subtalar arthritis.
- Recent reports of talar body fractures show a 20% rate of early superficial wound complications. All patients were treated effectively with oral antibiotics and local wound care. Thirty-eight percent of cases developed avascular necrosis. Evidence of talar dome collapse presented in half of these cases by 14 months after the injury. Patients with talar dome fractures with osteonecrosis and posttraumatic arthrosis had the lowest functional scores.
- No consensus exists regarding the most appropriate treatment of the extruded talus. This is a rare injury with an intuitively poor prognosis.
- A recent study evaluating reimplantation of the talus promoted the consideration of retaining the talus if possible. In the study, 8 patients had pure dislocations and 11
presented with various major and minor fracture patterns associated with talar extrusion. All fractures and dislocations were stabilized and no wound was allowed to granulate to closure. Talar collapse occurred within 1 year in all eight patients with major fractures. At an average of 42 months follow-up, there were two infections. Seven patients required secondary surgical procedures, including hardware removal, ankle arthroplasty with subtalar fusion, ankle fusion, bone grafting, débridement, and flap revisions. The authors clearly did not experience a high infection rate, supporting their conclusion that reimplantation is an effective solution to the challenging problem of traumatic tectomy.

COMPLICATIONS

- Fractures of the talus have known complications associated with soft tissue and fracture healing, malunion, arthrosis, and avascular necrosis.
  - Open fractures must be managed by a standard protocol including débridement, prophylactic antibiotics, fracture stabilization, and delayed closure.
  - Soft tissue complications associated with talus fractures are predominantly superficial.
    - If full-thickness slough occurs, however, a formal wound débridement is mandatory, followed by rotational or free flap coverage.
  - The incidence of delayed union or nonunion of fractures of the talar neck varies in the literature between 0% and 10%. The presence of avascular necrosis is a primary cause of nonunion. Nonunion of the talar neck fracture may also result from poor fixation.
  - If the cause of nonunion is unclear, the nonunion should be studied by magnetic resonance imaging or CT scan. Every effort should be made to revise fixation with autogenous bone graft when possible.
  - Nonunion due to total osteonecrosis of the body of the talus requires removal of the bone fragment and a tibiocalcaneal fusion.
  - Nonoperative management of comminuted lateral or posteromedial process fractures can be unpredictable.
    - If pain persists long after the patient has returned to full weight bearing and radiographic or CT imaging suggests nonunion, surgical resection of these fragments is routinely helpful. Pain is commonly linked to fibrous nonunion of these avulsion fragments.
  - Malunion of the talus is predominantly due to varus malalignment. Malalignment of the talar neck is best prevented using dual medial and anterolateral approaches in combination with the Canale image intraoperatively when performing the patient’s initial surgery.
  - Subtalar and ankle arthrosis is the most common complication associated with fractures of the talus. The incidence of subtalar arthrosis is greatest.
  - Arthritic symptoms can be managed effectively with non-steroidal anti-inflammatories. The hindfoot is also benefited by custom ankle bracing. The patellar tendon-bearing brace can effectively unload weight to the injured ankle, giving the patient increased relief.
  - If symptoms of arthrosis are not improved nonoperatively, the patient should be evaluated by selective hindfoot and ankle lidocaine injection. Relief of joint pain, whether unifocal or bifocal, will allow the surgeon to counsel the patient on further reconstructive treatment.

REFERENCES

DEFINITION

- An intra-articular calcaneal fracture is an injury that involves the joint surfaces of the calcaneus, usually with displacement.
- A fracture-dislocation of the calcaneus occurs when the posterior facet dislocates from beneath the talus and ends up displaced beneath the fibula. It carries a poor prognosis if treated nonoperatively.
- “Soft tissue” damage refers to the injury to the skin, adipose, tendinous, muscular, and nerve structures that surround the calcaneus and ranges from mild bruising to near-amputation in open fractures.
- Fracture blisters and varying degrees of skin contusion occur most commonly.
- “Wrinkle sign” refers to the skin wrinkles that appear when the injury swelling response is resolving.
- A primary fracture line is one that occurs early in the mechanism of the calcaneal fracture. There are two that occur, and if their pathogenesis is understood, this can explain the majority of the pathology observed. This will be defined further in the Pathogenesis section.

ANATOMY

- The calcaneus is the largest bone in the foot. It has a complex shape that makes exact surgical reconstruction difficult.
- The calcaneus functions to transmit weight-bearing forces of the leg into the foot.
- The calcaneus has a shock absorber function by assisting in mobility of the ankle and subtalar joints, thus allowing the foot to accommodate to variations in terrain.
- The calcaneus has four articular facets that produce this mobility: posterior, anterior, middle, and cuboid. Exact articular alignment is required for full function of this four-joint complex.
- The internal structure of the calcaneus reflects its weight-bearing role.
  - There is particularly dense trabecular bone in the juxta-articular regions, especially below the posterior facet (the thalamic trabecular system).
  - The tendo Achilles insertion also has dense trabecular bone.
- Cortical bone of 3 to 4 mm in thickness occurs in the superior-medial region (sustentaculum area) and in the superior-lateral strut of bone that runs between the cuboid and posterior facets (anterolateral fragment). These regions of cortical bone will come into play when discussing the internal fixation of the calcaneus (FIG 1).
- The soft tissues of the calcaneus are easily damaged by trauma. Management of this injury component is essential to avoid iatrogenic surgical complications.

PATHOGENESIS

- Despite the seemingly infinite varieties of fractures that occur, stereotypic fracture lines, fragments, and displacements can be recognized.
- The calcaneus is fractured by a combination of shear and compression forces generated by the talus descending upon the calcaneus.
- Two primary fracture lines occur.
  - The first occurs in the angle of Gissane and divides the calcaneus into anterior and posterior fragments. It can split either the middle or anterior facet, and the fracture continues on the lateral wall in an inverted Y shape (FIG 2).
  - The second fracture divides the calcaneus into medial and lateral halves and shears the posterior facet into two or more fragments.
    - As the talus continues to compress the calcaneus, the lateral half of the posterior facet is impacted into the body of the calcaneus, with the recoil producing a step-off in the posterior facet.
    - This same fracture line commonly continues into the cuboid facet and, in combination with the first primary fracture line, produces the anterolateral fragment and superomedial fragment.
    - In this way, these two fracture lines produce fracture components that include the superomedial fragment, anterolateral fragment, posterior facet, and tuberosity.
  - Characteristic displacements of these components occur.
    - The tuberosity is driven up between the pieces of the posterior facet, can tilt into valgus or varus, and is usually translated laterally.
    - The lateral posterior facet fragments are impacted and rotated plantarily into the body of the calcaneus (FIG 3A).
    - The posterior facet breaks into one of three patterns, which form the basis of the Sanders classification:
      - Sanders II: two main pieces (FIG 3B)
      - Sanders III: three main pieces (FIG 3C)
      - Sanders IV: multifragmentary
    - The superomedial fragment retains alignment to the talus by means of its ligamentous attachments but can be subtly displaced by overlap with the anterior process. This overlap occurs along the primary fracture line that occurs in the sinus tarsi.
    - The anterolateral fragment displaces superiorly a variable amount. It typically extends into the cuboid facet, with varying degrees of displacement (FIG 3D).
    - The lateral calcaneal wall is displaced outward in the area of the trochlear tubercle. This, in combination with tuberosity translation, accounts for the heel widening and peroneal impingement that occur.
The first fracture types recognized were the joint depression and tongue-type patterns, which are readily identified on a lateral heel radiograph. The tongue fracture maintains a connection between the tuberosity and the posterior facet, while the joint depression separates the fractured joint surface from the tuberosity (FIG 4).

Because of this anatomy, certain tongue fractures have a large portion, or even the entire posterior facet, in continuity with the tuberosity (AO-OTA 73 C1). Thus, reduction of the tongue fracture is important to maintain the connection with the tuberosity.

FIG 1 • A lateral radiograph of a calcaneus specimen sectioned in the sagittal plane. The trabecular systems are visualized and numbered 1 through 4. The densest bone is in the juxta-articular regions. Thick cortical bone also is present in the anterolateral fragment and medial wall in the sustentacular region. 1, thalamic trabecular system; 2, anterior apophyseal trabecular system; 3, anterior plantar trabecular system; 4, posterior plantar.

FIG 2 • Pattern of calcaneal fracture-dislocation and reduction.

FIG 3 • A. The posterior facet displaces and rotates in a plantar direction (arrow). B,C. CT scans showing a Sanders II fracture with a large superomedial fragment (B) and a Sanders III fracture (C). D. The primary fracture line extends into the calcaneal cuboid facet. The anterolateral fragment is represented by the most lateral piece (arrow). (D: Courtesy of Paul Tornetta III, MD.)
the tuberosity will reduce indirectly the posterior facet and restore the angle of Bohler. This particular pattern is well suited for small incision or percutaneous techniques.

- Reduction of a joint depression pattern is best performed with an open reduction.

**NATURAL HISTORY**

- An intra-articular fracture of the calcaneus is a serious injury that will diminish foot function.
- Nonoperative treatment is with early motion and delayed weight bearing 6 to 8 weeks after injury. This method has the least chance of iatrogenic injury.
- In a classic review by Lindsay and Dewar, only 17% of patients had no foot symptoms with long-term follow-up.
- The loss of ability to perform manual labor is common, with an average time off work of 4 to 6 months for laborers.
- Loss of subtalar motion to varying extents will occur.
- Tibiotalar impingement and anterior ankle pain can be produced if the crush deformity is severe enough.
- It can take 18 to 24 months for the foot symptoms to maximally improve after this injury. Most improvement occurs in the first 12 months.
- The key concept here is that patients who continue to improve symptomatically can be observed until maximum improvement occurs.
- A recent randomized, prospective study found that the need for late subtalar arthrodesis is five to six times greater if nonoperative treatment is used on all injuries. The overall rate was approximately 17%.

**PATIENT HISTORY AND PHYSICAL FINDINGS**

- The history is typically one of a fall or vehicle crash. Occasionally in a diabetic, a seemingly trivial ankle sprain-type mechanism can occur. Important risk factors for operative treatment complications include smoking, diabetes, peripheral vascular disease, and steroid use. The foot and ankle are visually inspected.
- Swelling is graded as mild, moderate, or severe.
- Operative treatment in the face of severe soft tissue swelling is prone to wound healing complications.
- Fracture blisters are graded as fluid-filled or blood-filled. If unhealed, fracture blisters are a source of skin bacterial colonization. Blood-filled blisters denote a deeper dermal injury.
- Skin contusion is noted.
- If present, the wrinkle sign is noted. It means the swelling is resolving and surgical incisions are less likely to experience complications.
- Open wounds are noted.
- The physician palpates the foot and ankle, looks for spine injuries or ipsilateral fractures, and performs a secondary survey for other injuries.
- Spine injuries are said to accompany up to 10% of all calcaneal fractures.
- The physician assesses for compartment syndrome, including passive flexion and extension of the toes, tenseness of the foot swelling, and compartment pressure measurement.
- Positive results are degree of pain elicited and pressures within 30 mm of diastolic blood pressure.
- Compartment syndrome can occur in 5% to 10% of all calcaneal fractures.
- The physician performs a neurologic examination to check the sensory function of foot and toes, including light touch and pinprick.
- Calcaneal fractures can damage the posterior tibial nerve and occasionally sensory nerves. Findings may be altered with compartment syndrome.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Anteroposterior and lateral (FIG 5A,B) foot radiographs are the initial screening study.
- The axial (Harris) view should also be obtained (FIG 5C). This view will demonstrate the medial wall and show the relation of the superomedial fragment to the tuberosity.
- Broden views are radiographs that focus on the subtalar joint. They are taken with the foot internally rotated, and the x-ray beam angled to varying degrees cephalad (FIG 5D,E). By using different degrees of cephalad angulation, different parts of the posterior facet may be imaged. They are best used intraoperatively to judge the reduction of the posterior facet and the medial wall of the calcaneus.
If the fracture is displaced, a computed tomography (CT) scan is recommended to define the anatomy (see Fig 3B,C).

A CT scan with biplanar cuts and reconstructions is recommended. This will best delineate the fragments and displacements.

DIFFERENTIAL DIAGNOSIS

- Fracture of the talus
- Lateral process of talus fracture
- Fracture of the midfoot (eg, navicular fracture)
- Severe ankle sprain
- Subtalar dislocation
- Stress fractures of the calcaneus can masquerade as a soft tissue disorder of the hindfoot (eg, plantar fasciitis).

NONOPERATIVE MANAGEMENT

- The indications for nonoperative treatment include posterior facet displacement less than 2 mm, and medical conditions such as peripheral vascular disease or diabetes.
- Some surgeons consider smoking a relative contraindication; it certainly predisposes to a higher wound complication rate.
- Severe fracture blisters or closed soft tissue injury can preclude operative treatment, although open reduction and internal fixation can be performed as late as 4 weeks after injury.

The recommended nonoperative treatment is compression wrapping, early motion, and delayed weight bearing at 6 to 8 weeks after injury. This offers the least iatrogenic risk to the patient while optimizing chances for subtalar motion.

- Once weight bearing is started, the patient continues with range-of-motion exercises.
- Strengthening of the foot and ankle muscles is added as fracture consolidation progresses.
- A well-cushioned shoe usually offers the best pain relief. Two different shoe sizes may be needed in extreme cases.
- A rocker-bottom sole can be added to assist with the toe-off stance phase of gait.
- A double upright brace with a rocker-bottom-soled shoe can assist ambulation in patients with severe injury who have impairment upon fracture healing.

Nonoperative treatment is not recommended for calcaneal fracture dislocations, as a painful deformed foot is practically guaranteed if it is left unreduced.

SURGICAL MANAGEMENT

- The displaced intra-articular calcaneal fracture presents a difficult challenge.
- Foot pain and stiffness are common even with the best of treatment, and iatrogenic problems such as infection can result in loss of limb in extreme circumstances, and at the least predispose to a poor result.
Thus, a careful, individualized approach is recommended, with a priority on avoiding iatrogenic problems while attaining an anatomic alignment of the calcaneus.

- Indications include displacement of the posterior facet of more than 2 mm, and calcaneus fracture dislocation.
- Research shows that certain patient groups, such as those receiving worker’s compensation, are predisposed to a poor result with operative treatment, but that does not obviate the benefits of obtaining anatomic foot alignment and lessening the chances of late subtalar fusion.
- Operative restoration of at least the calcaneal shape should be considered for fractures with severe displacement (e.g., tuberosity displaced superiorly behind the ankle joint), as late reconstructions can be difficult.
- The choice of any surgical approach or technique should always have the goal of total anatomic restoration, although extreme comminution can compromise attainment of this goal.

Preoperative Planning

- Once operative treatment has been elected, the surgical approach is chosen based on a number of factors, including the surgeon’s training and experience and the pathoanatomy present.
- The timing is in general when the wrinkle sign develops, typically 7 to 14 days after injury. Fracture blisters should be epithelialized.
- The injury pathoanatomy is analyzed first by looking at the posterior facet pattern (Sanders II, III, or IV), displacement, and location of the primary fracture line in the posterior facet.
- Fractures that are more medial are more difficult to visualize, and more fragments involving the posterior facet are more difficult to fixate anatomically.
- Fractures that separate the entire posterior facet and have a tongue pattern are amenable to percutaneous Essex-Lopresti techniques.
- Conversely, joint depression fractures require open reduction of the posterior facet.
- A highly comminuted Sanders IV fracture may alter the goals to restoration of the calcaneal body shape and primary fusion.
- The other fracture components to be analyzed for displacement are the superomedial fragment, anterolateral fragment, and tuberosity. The surgical plan should address each of these pathologies for reduction strategy and fixation.
- The typical reduction order is first to correct any superomedial fragment subluxation.
- Next, the superomedial fragment is reduced and held to the tuberosity.
- The posterior facet is then reduced and fixed.
- Finally, the anterolateral fragment is reduced and fixed.
- The size and integrity of the superomedial fragment is critical, as fixation techniques largely center on screw placement into its substance. A small or comminuted superomedial fragment makes rigid fixation harder to achieve and may call for alternative techniques.
- Restoration of the superomedial fragment to the tuberosity will restore the calcaneal shape and make room for reduction of the displaced posterior facet fragments.
- The superomedial fragment may be incarcerated in the sinus tarsi and subtly subluxated. This is recognized by the preoperative CT scan on the sagittal reconstructions, and by the lack of congruence of the superomedial fragment with the undersurface of the talus.
- Failure to correct this subluxation makes posterior facet reduction very difficult.
- The anterolateral fragment should key into location just in front of the reduced posterior facet and restores lateral column length.
- It can be fixed with either lag screws into the superomedial fragment, or a mini-fragment plate. Some of the perimeter plates have a small extension to pull this fragment into place.
- The fixation chosen depends on the approach taken. Fractures splitting the posterior facet will require lag screws inserted from lateral to medial; they range in size from 2 to 4 mm, depending on the fractures present.
- Sanders III fractures are converted into two major pieces with the use of countersunk mini-fragment screws that fix the intermediate piece to the more medial piece.
- Extra-long mini-fragment screws are desirable to reach the medial cortical bone.
- The plate chosen depends on the approach.
- The extensile lateral approach will require some type of low-profile “perimeter” plate.
- Strategic placement of small and mini-fragment plates, and occasionally lag screws alone, is used in small-incision techniques.
- Plans must be made for imaging, most typically fluoroscopy. This will allow control of the AP, lateral, axial, and Broden views intraoperatively.
- Arthroscopy can also help visualize the posterior facet, especially in its anterior portions.

Positioning

- The extensile lateral approach is performed in the lateral decubitus position with the injured foot on top. A thigh tourniquet is applied.
- The fluoroscope is brought in from the side opposite the surgeon regardless of the surgical approach.
- The same position can be used for percutaneous manipulations of tongue fractures. This allows conversion to the extensile lateral approach, as recommended by Tornetta.
- Small-incision approaches are performed supine with a bump under the ipsilateral hip. A tourniquet is placed but not routinely inflated.
- For small-incision techniques, the patient is pulled down to the end of the table. The point of the heel should project slightly beyond the end of the bed. This allows for placement of axially directed implants.
- If used, the arthroscope is placed with the monitor on the same side as the C-arm, toward the head of the bed.

Approach

- Small-incision techniques will address most calcaneal pathologies but require a firm understanding of the fragments, displacements, and deforming forces present.
- They are ideally suited to Sanders II fractures with a large superomedial fragment and only mild to moderate posterior facet displacement.
- The extensile lateral approach is applicable to all fracture patterns and displacements. Its use in open fractures warrants caution with respect to soft tissue complications.
PERCUTANEOUS REDUCTION AND FIXATION OF TONGUE FRACTURE

- If performed acutely, percutaneous reductions can be technically easier and do not increase the risk of infection in my experience.
- If there is any question, the surgeon should use the presence of the wrinkle sign and healing of fracture blisters.
- This technique is ideally indicated for tongue patterns that have a large percentage of the posterior facet connected to the tuberosity (Sanders IIC) (TECH FIG 1A).

- The technique can be used for Sanders IIA and IIB patterns, but the facet reduction is more difficult if done percutaneously.
- I prefer to perform this surgery supine, with the addition of a sinus tarsi incision for failure of the percutaneous reduction.
- Tornetta prefers the lateral position, with conversion to the extensile lateral approach if percutaneous manipulations are unsuccessful.

**TECH FIG 1**

A. A displaced tongue fracture demonstrates the typical displacement and location of an injury amenable to percutaneous reduction. The anterior process is not comminuted. The medial fragment was small.

B. Introduction of a large smooth pin to manipulate the fracture. Note the incomplete reduction in the angle of Gissane, and posteriorly where the tongue fracture exits.

C. Multiple wires for cannulated screws have been placed. The anterior process is not comminuted and can be used for screw purchase.

D. Reduction obtained and screw placement.

E–G. For this Sanders II fracture, after repair of the navicular fracture, a small incision was made in the plantar lateral foot, localizing the area beneath the angle of Gissane. E. A 5-mm pin was placed on a Synthes (Paoli, PA) T-handled chuck. The pin was then placed through the stab incision and advanced just inside the lateral wall of the calcaneus. At the same time, a cannulated screw guidewire was placed in the plantar portion of the calcaneus.

F. With the manipulating pin applying a firm upward pressure with the foot plantarflexed, the wire was driven from the tuberosity into the tongue fragment. This was replaced with a 4.0-mm cannulated screw.

G. A second cannulated screw was placed from the lateral calcaneus into the superomedial fragment.
The patient is placed supine with a generous bump under the ipsilateral hip to assist access to the heel.

0.25% Marcaine with epinephrine is injected into the fracture hematoma and soft tissues. A popliteal block is also placed by the anesthesia team. The combination of these two blocks will allow for outpatient surgery management of this injury.

A 1/8 Steinmann pin is introduced into the calcaneus from the posterior tuberosity into the region just beneath the posterior facet.

The pin is then used as a levering tool to restore the Bohler angle of the fractured calcaneus (TECH FIG 1B).

Taking a lateral view of the normal heel and saving it on the fluoroscope provides a comparison to judge reduction. Once the fracture is reduced, one or two cannulated screws are introduced from the tuberosity into the anterior process of the calcaneus (TECH FIG 1C,D).

Alternative or adjunctive fixation strategies include placing a 4.0-mm screw from the plantar tuberosity into the dorsal calcaneus surface. This resists plantar displacement of the tongue fragment.

Another lag screw possibility is one directed from the lateral calcaneus into the superomedial fragment (TECH FIG 1E–G). This is more difficult in this pattern because by definition it has a small superomedial fragment.

OPEN REDUCTION

If the Bohler angle is not reducible or if a step-off remains in the posterior facet, an open reduction is performed.

I prefer a small sinus tarsi incision approach to aid in the reduction.

A 4- to 6-cm sinus tarsus incision is made to expose the posterior facet, the anterolateral fragment, and a portion of the lateral calcaneal wall (TECH FIG 2).

The posterior facet is reduced under direct vision, and the reduction is confirmed with fluoroscopy. An arthroscope is helpful as well.

A traction pin in the tuberosity can help restore calcaneal height.

Lateral to medially directed lag screws are placed across the posterior facet. A mini-fragment plate is used to bridge the posterior facet to the anterolateral fragment.

The lateral wall should be manually compressed at this point.

Consideration can be given to adding a calcium phosphate cold hardening composite to provide extra support.

Layered closure is performed.

TECH FIG 2 • Lateral approach for the small incision technique.

SIMULTANEOUS MEDIAL AND LATERAL APPROACHES

In general, except for open fractures, timing should be guided by the presence of the wrinkle sign and healing of fracture blisters.

This technique is ideally indicated for Sanders II fractures with 2 to 10 mm of displacement of the posterior facet, and a large superomedial fragment. It can be applied to nearly any fracture pattern, but the limited exposure makes posterior facet reduction more difficult for Sanders III and IV patterns.

A generous bump is placed under the ipsilateral hip. The heel is left slightly off the end of the bed to facilitate the placement of axially directed fixation.

0.25% Marcaine with epinephrine is injected into the fracture hematoma and soft tissues. A popliteal block is also placed by the anesthesia team.

The combination of these two blocks will allow for outpatient surgery management of this injury.

Injuries and Dissection

The medial approach is posterior and parallel to the neurovascular bundle (TECH FIG 3A).

The medial calcaneal sensory branch is identified deep to the flexor retinaculum and preserved. This directly exposes the superomedial fragment and keeps the neurovascular bundle in the anterior flap.

The lateral approach extends anteriorly 4 to 6 cm from the tip of the fibula (see Tech Fig 2).

This will provide exposure of the posterior facet and anterolateral fragment.

It is performed after the medial approach.
■ At this point, all fracture fragments are identified and cleaned of debris.
■ The posterior facet is partly reduced to avoid obstruction of the superomedial fragment and tuberosity reduction.
■ A 1.6-mm Steinmann pin is introduced into the tuberosity of the calcaneus in a medial-to-lateral direction. Tensioned with a Kirschner bow, it allows for correction of shortening (TECH FIG 3B).
■ The medial fracture fragments are cleaned of debris, and landmarks for reduction are identified.

### Medial Reduction and Fixation
- Reduction and fixation can be done with one of two strategies.
- The first is with an antiglide 2.7-mm plate.
  - One can predrill a hole on the tuberosity fragment next to the fracture site and to the length measured.
  - With use of distraction and manipulation, an approximate reduction of the superomedial fragment and tuberosity is obtained, particularly with respect to length.
  - A 2.7-mm five-hole T plate is then placed on the bone and the premeasured screw inserted. As the plate tightens to the bone, it will help reduce any tuberosity translation (TECH FIG 4).
- The reduction is checked by fluoroscopy in all planes.
- If satisfactory, additional screws can be inserted, taking care to avoid the posterior facet.
- The second method is to obtain a reduction by traction and translation of the tuberosity.
  - One can then introduce axial cannulated screws—one up the inside of the medial wall and the other as a lag screw from the inferior lateral tuberosity into the superomedial fragment.
  - This latter lag screw is a useful adjunct to a medial antiglide plate.

### Lateral Reduction and Fixation
- Once the medial side is reduced, the lateral side is addressed.
The posterior facet is manipulated and reduced. The reduction is checked with Broden views and the arthroscope (TECH FIG 5).

It is common to approximate one portion of the facet, only to have another portion malreduced.

Once an anatomic reduction is obtained, provisional fixation with Kirschner wires is performed. Two lateral-to-medial-directed lag screws are then inserted just beneath the articular surface of the posterior facet.

The anterolateral fragment will now reduce anatomically to the posterior facet. It can be fixated with either a mini-fragment plate that bridges from the posterior facet to the anterolateral fragment, or a lag screw from the anterolateral fragment to the superomedial fragment.

The lateral wall should be manually compressed at this point.

Consideration can be given to adding a calcium phosphate cold hardening composite to provide extra support.

Layered closure is performed.

EXTENSILE LATERAL APPROACH

Timing should be guided by the presence of the wrinkle sign and healing of fracture blisters. This can take up to 3 weeks.

This technique is indicated for all types of calcaneal fractures with intra-articular displacement. Open fractures are best approached in a staged fashion.

The lateral decubitus position is used, with the injured side up. The C-arm comes in opposite the surgeon.

0.25% bupivacaine with epinephrine is injected into the fracture hematoma and soft tissues. A popliteal block is also placed by the anesthesia team. Tourniquet control is required.

An L-shaped incision is made parallel to the Achilles tendon and curves anteriorly along the border of the plantar skin of the heel (TECH FIG 6A).

The incision is made to bone, with a subperiosteal and periosteal flap raised along its entire extent. In the region of the peroneal tendon sheath attachment, the tendons are retracted anteriorly and the dissection is continued on the deep layer, above the abductor fascia.

Once the entire lateral side of the calcaneus is exposed, two Kirschner wires can be driven into the talus to provide retraction of the flap (TECH FIG 6B).

The lateral wall is entered and the posterior facet elevated from its displaced position (TECH FIG 6C).
If the superomedial fragment is subluxated by the anterior process, this is corrected by leverage and a Kirschner wire driven across the reduced fragments.

- A Schanz screw is driven into the tuberosity to facilitate manipulation of the fragments. Alternatively, a tensioned wire can be used.

- Attention is turned to the medial wall, where the superomedial fragment is identified.

- With traction and manipulation of the pieces, the medial wall is reduced and pinned with axial Kirschner wires that travel just inside the medial wall of the calcaneus.

- The posterior facet can now be reduced and provisionally fixated with Kirschner wires, and lateral-to-medial—directed lag screws are placed. Broden views are essential to ensure anatomic reduction.

- The anterolateral fragment is reduced to the posterior facet and pinned into the superomedial fragment.

- A perimeter plate is now applied to the lateral surface of the calcaneus (TECH FIG 6D,E). Contouring of the plate is not recommended, except in the area next to the curved posterior portion of the posterior facet if needed. It functions in a sense as a giant washer, serving to compress the calcaneus from lateral to medial.
PEARLS AND PITFALLS

| Indications | • Less invasive approaches require an accurate definition of the pathoanatomy, then matching the pathoanatomy with an operative plan.  
• Extensile approaches should be used cautiously with open fractures. |
| --- | --- |
| Fracture reduction | • With open approaches, the order of reduction is the same: superomedial fragment to anterior process, superomedial fragment to tuberosity, posterior facet to superomedial fragment, anterolateral fragment to posterior facet, lateral wall.  
• Exact posterior facet reduction is difficult to achieve but required to achieve excellent results. Adjuncts of fluoroscopy and arthroscopy help visualize the highly congruent subtalar joint.  
• In Sanders III fractures, the intermediate piece can be fixated to the superomedial fragment with 2.0-mm lag screws, thus converting it to a Sanders II pattern. |
| Fracture implants | • Extra-long mini-fragment screws are essential to allow matching of screw and fragment size, especially in the posterior facet.  
• The application of a straight plate to the lateral calcaneal surface will avoid varus of the heel. |
| Complications | • Strict foot elevation until suture removal is recommended to assist in wound healing. |
| Postoperative care | • Reliable patients without diabetes can safely perform touch-down range-of-motion exercises to assist in recovery of subtalar motion. |

POSTOPERATIVE CARE

• A well-padded short-leg cast is applied, split, and overwrapped with a loosely applied elastic wrap.  
• The patient is instructed to maintain strict elevation as much as possible until the sutures are removed.  
• The same cast is retained until the sutures are removed 2 weeks postoperatively.  
• In reliable nondiabetic patients, the cast can be discontinued and range-of-motion exercises begun.  
• Touch-down weight bearing to promote ankle and subtalar motion can be started at the same time.  
• Physical therapy is prescribed on an individualized basis.  
• At 6 weeks, a radiograph is obtained and weight bearing progressed as pain allows. Full weight bearing is expected by 12 weeks postoperatively.

OUTCOMES

• Despite appropriate care, most patients with a calcaneal fracture will lose some degree of foot function and have permanent symptoms.  
• While nonoperative treatment yields the fewest iatrogenic complications, it accepts malunion in nearly 100% and a higher incidence of later subtalar fusion.

• Symptom improvement can take up to a year to plateau.  
• In a recent randomized study, visual analog pain scores between nonoperative and operative groups were similar, but nonoperative treatment resulted in a 5.5 times greater incidence of late subtalar fusion.  
• In that same study, females, non-workmen's-compensation cases, and nonmanual laborers had improved results with operative treatment.  
• Better results were also seen with an anatomic reduction versus a nonanatomic one.  
• Soft tissue complications frequently lead to a poor result.  
• Amputations have been reported with extensile lateral approaches.  
• Open techniques should be used cautiously in diabetic patients, although injuries such as fracture-dislocation are best treated with operative reduction and fixation.

COMPLICATIONS

• The complications of nonoperative treatment include malunion, persistent foot pain, and a higher chance of later subtalar fusion.  
• Severe crush deformities affect not only the subtalar joint, but the midfoot and ankle as well. They can be difficult to
reconstruct, so initial management to avoid such a malunion is recommended.

- Smoking, diabetes, and open fracture are the most significant risk factors for soft tissue complications.
- Infection occurs in about 2% of fractures treated operatively with open incisions.
- Flap necrosis can occur with any incision but is most likely with the extensile lateral approach. Débridement and closure by secondary intention is often successful for minor flap losses. If a large portion of the flap is lost, consultation with a plastic surgeon is recommended.
- Deep infection is managed with débridement and intra-venous antibiotics based on culture results.
- Retention of hardware (if providing bone stability) until bone healing is optimal.
- Removal of the hardware to eradicate the infection once the bone is healed is sometimes needed.
- Posterior tibial nerve injury can result from the fracture and commonly presents with severe pain nonresponsive to narcotics in the postinjury period.
- Administration of medications aimed at neuropathic pain is recommended, and consultation with a pain specialist is considered.
- Cushioned shoe inserts are often comforting to individuals with postfracture plantar heel pain. A rocker-bottom shoe can also reduce discomfort.
- Late implant-related symptoms are rare with percutaneous or small-incision techniques. They are lessened by the use of low-profile “perimeter” plates with the extensile lateral approach.

REFERENCES

DEFINITION
- A Lisfranc injury refers to bony or ligamentous compromise of the tarsometatarsal and intercuneiform joint complex and includes a spectrum of injuries ranging from a stable, partial sprain to a grossly displaced and unstable fracture or fracture-dislocation of the midfoot.

ANATOMY
- The bony elements of the medial three tarsometatarsal joints (medial, middle, and lateral cuneiforms and first, second, and third metatarsal bases) feature a unique trapezoidal shape in cross-section, creating a concave arrangement plantarly resembling a Roman arch (FIG 1A).
- The second metatarsal is recessed between the medial and lateral cuneiforms in the axial plane and is positioned at the apex of the Roman arch in the coronal plane. It thus functions as the keystone of the entire midfoot complex (FIG 1B).
- The tarsometatarsal joints are stabilized by dorsal and plantar tarsometatarsal ligaments.
- Dorsal and plantar intermetatarsal ligaments provide further stability between the second through fifth metatarsal bases.
- There are no intermetatarsal ligaments between the first and second metatarsals, which may predispose the area to injury.
- The Lisfranc ligament courses from the plantar portion of the medial cuneiform to the base of the second metatarsal (FIG 1C).
- The unique bony arrangement of the medial midfoot imparts inherent bony stability to the medial and middle columns of the foot, which in combination with the stout plantar ligaments prevents plantar displacement of the metatarsal bases and facilitates the weight-bearing function of the first ray (FIG 2).
- The medial three tarsometatarsal joints and the adjacent intercuneiform and naviculocuneiform articulations (medial and middle columns) have limited inherent motion, making these joints nonessential to normal foot function and therefore relatively expendable.
- The medial column refers to the first tarsometatarsal and navicular–medial cuneiform articulations; the middle column includes the second and third tarsometatarsal joints, and articulations between the navicular and middle and lateral cuneiforms, respectively.
- The fourth and fifth tarsometatarsal (lateral column) joints have distinctly more inherent motion and are critical in accommodation of the foot to uneven surfaces.
- These joints are considered essential joints to normal foot function and therefore nonexpendable.

PATHOGENESIS
- Lisfranc injuries are generally the result of a high-energy injury, such as a fall from a height or a high-speed motor vehicle accident, but depending on the position of the foot, they may also result from a lower-energy injury, such as a slip and ground-level fall.
- These injuries result from a combination of axial load, and dorsiflexion, plantarflexion, abduction, or adduction (or variable combinations thereof) of the midfoot.
- The pathoanatomy is individually specific and highly variable and may consist of a pure ligamentous injury, a pure bony injury (fracture), or a combination.
- While the injury classically includes the first, second, and third tarsometatarsal joints, there may be involvement of all five tarsometatarsal articulations, extension into the intercuneiform joints, or even fracture lines into the navicular or cuboid proximally, or metatarsal shafts or necks distally.
- In pure ligamentous patterns, the stability of the injury depends on the status of the plantar tarsometatarsal ligaments. Disruption of these stout structures makes the injury unstable.
- Partial injuries (sprains) occur as a result of lower energy and are more common with axial load and plantarflexion, such as in competitive sports.
- In this instance, by definition the plantar tarsometatarsal ligaments remain intact, making the injury stable.

NATURAL HISTORY
- Stable injuries (partial sprains, extra-articular fractures) often require prolonged recovery time. When accurately diagnosed, however, patients with these injuries can generally expect full recovery and return to activity with minimal long-term implications.
- Unstable injuries that are misdiagnosed or inadequately treated generally go on to a poor result with persistent pain, activity limitations, and progressive posttraumatic arthritis in the involved joints, necessitating arthrodesis as salvage.
- A high index of suspicion must therefore be maintained; historically up to 20% of unstable Lisfranc injuries are misdiagnosed on plain radiographs.

PATIENT HISTORY AND PHYSICAL FINDINGS
- The physician should obtain a history of trauma and details of the exact injury mechanism (position of foot, direction of force, extent of energy involved).
- The physician should observe any initial swelling and inability to bear weight.
- A thorough examination of the involved foot and ankle also includes assessment of associated injuries and any other areas of swelling or tenderness to palpation.
- The physician should observe the skin and soft tissue envelope. Diffuse swelling of the midfoot or plantar ecchymosis at the midfoot suggests a Lisfranc injury.
- The physician should palpate the midfoot joints; pain at the midfoot with palpation suggests a Lisfranc injury (see Exam Table for Pelvis and Lower Extremity Trauma, pages 1 and 2).
The physician should test midfoot stability with passive flexion of the metatarsal heads and passive abduction and adduction through the forefoot. Pain at the tarsometatarsal joint region with passive forefoot range of motion suggests a Lisfranc injury.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Initial radiographic evaluation consists of non-weight-bearing anteroposterior (AP), oblique, and lateral views of the foot, which, depending on the extent of intra-articular displacement, may provide sufficient diagnostic information (FIG 3A–C).
- Fluoroscopic stress views may be helpful in more subtle injuries; however, these studies are painful and generally require anesthesia.
- We therefore prefer weight-bearing radiographs of the foot for more subtle injuries (FIG 3D–H); comparison weight-bearing radiographs of the contralateral foot may also be obtained where necessary.
- The weight-bearing AP view of the foot will demonstrate intra-articular displacement through the first and second tarsometatarsal joints (so-called Lisfranc joint), intercuneiform joint, and naviculocuneiform joint; fractures through the first and second metatarsal bases, medial and middle cuneiforms, and proximal extension into the navicular; and the extent of columnar shortening or asymmetry.
- The medial border of the second metatarsal should align with the medial border of the middle cuneiform (FIG 3D).
- The oblique view will reveal intra-articular displacement through the third, fourth, and fifth tarsometatarsal joints, and fractures of the third, fourth, and fifth metatarsal bases, lateral cuneiform, and cuboid.
- The medial borders of the third and fourth metatarsals should align with the medial borders of the lateral cuneiform and cuboid, respectively (FIG 3E).
- The lateral view may reveal dorsal–plantar displacement of fractures or dislocations, as well as any flattening of the medial longitudinal arch, thereby reflecting the status of the weight-bearing medial column and first ray (FIG 3F).
- Computed tomography (CT) scanning may also be beneficial in the instance of a subtle Lisfranc injury, particularly in a polytrauma patient or a patient with multiple extremity injuries that preclude weight-bearing radiographs; and to delineate proximal fracture line extension into the navicular, cuboid, or cuneiforms (FIG 4).

**DIFFERENTIAL DIAGNOSIS**

- Partial Lisfranc injury (sprain)
- Isolated metatarsal fracture
- Navicular–cuneiform fracture
- Anterior process of calcaneus fracture
- Lateral ankle sprain

**NONOPERATIVE MANAGEMENT**

- Nonoperative treatment is indicated for partial Lisfranc injuries (sprains), which by definition are stable and therefore nondisplaced on weight-bearing radiographs.
- Nonoperative treatment is also indicated for nondisplaced or minimally displaced extra-articular metatarsal base fractures with no intra-articular involvement (displacement) on weight-bearing radiographs.
- Because of the often subtle nature of Lisfranc injuries and the negative consequences of misdiagnosis, if the findings are inconclusive, weight-bearing radiographs may be repeated 2 to 3 weeks after the injury.
- Nonoperative management consists of immobilization in a venous compression stocking and prefabricated fracture boot.
- The patient is allowed to bear weight to tolerance, and early progression to range of motion is encouraged.
- The patient continues in the fracture boot for 5 to 6 weeks, at which point maintenance of alignment or radiographic union is confirmed on repeat weight-bearing radiographs.
- The patient is then allowed to wear regular shoes, and activities are advanced as tolerated thereafter.
- Full recovery and return to sports or other rigorous activity may require up to 3 to 4 months.
FIG 3 • Non-weight-bearing AP (A), oblique (B), and lateral (C) radiographs of grossly unstable, purely ligamentous, Lisfranc dislocation involving all five tarsometatarsal articulations. Marked lateral subluxation through all five tarsometatarsal joints is evident on the AP and oblique views, and significant dorsal displacement is evident on the lateral view. Weight-bearing lateral (D), AP (E), and oblique (F), and non-weight-bearing (G) and oblique (H) radiographs of more subtle Lisfranc injury. Lateral and plantar subluxation (black arrows) is evident on the weight-bearing radiographs, and displacement of normal radiographic landmarks (black lines) confirms injury.
Surgical management is indicated for unstable (displaced) injuries of the midfoot, including pure ligamentous, bony, or variable combinations. Recent studies suggest that pure ligamentous Lisfranc injuries are best managed with open reduction and primary arthrodesis of the medial and middle columns. Any dislocation producing tension on the overlying skin and soft tissue envelope should be immediately reduced and immobilized. Definitive surgery is generally delayed 10 to 14 days to allow adequate resolution of soft tissue swelling.

Preoperative Planning

- The injury and weight-bearing radiographs and CT images are reviewed and the injury is classified, which allows planning for the anticipated pathoanatomy of the injury.
- Pure ligamentous injuries require rigid screw fixation for the medial and middle column joints and Kirschner wire fixation for the lateral column joints; bony injury patterns, particularly those with more comminution, may require minifragment bridge plate fixation.

Positioning

- The patient is placed supine with a bolster beneath the ipsilateral hip. Protective padding is placed around the contralateral limb, primarily to protect the peroneal nerve, and the contralateral limb is secured to the table.
- A sterile bolster is placed beneath the operative limb at the knee to facilitate access to the midfoot and intraoperative fluoroscopy.

Approach

- We prefer the dual-incision approach. The medial incision courses directly over the extensor hallucis longus (EHL) tendon and is centered over the first tarsometatarsal joint. It affords access to the first and second tarsometatarsal joints.
- The lateral incision is centered over the lateral border of the third tarsometatarsal joint. If extended, it also provides exposure to the fourth and fifth tarsometatarsal joints where necessary.
- A third, more proximal and lateral incision may be required to stabilize the cuboid where necessary.
- Because of the limited soft tissue envelope overlying the midfoot, the importance of meticulous soft tissue handling and maintaining full-thickness soft tissue flaps cannot be overemphasized.
MEDIAL INCISION

- The medial incision is made directly over the EHL tendon and is centered over the first tarsometatarsal joint.
  - The tendon sheath is incised dorsally, and the EHL is retracted laterally (TECH FIG 1A).
- The floor of the tendon sheath is then incised and subperiosteal dissection commences medially, extending to the medial margin of the first tarsometatarsal joint and producing a full-thickness flap.
- Subperiosteal dissection then extends laterally to the lateral margin of the second tarsometatarsal joint, again producing a full-thickness flap, while preserving the adjacent neurovascular bundle within the soft tissue flap (TECH FIG 1B).
- The status is noted of each of the tarsometatarsal and intercuneiform joint capsules dorsally, and therefore the extent of instability of each joint (TECH FIG 1C,D).
- We prefer using the medial (EHL) incision for access to the second tarsometatarsal and intercuneiform joints, even if the first tarsometatarsal joint is not involved, because the neurovascular bundle remains protected within the full-thickness flap.

LATERAL INCISION

- A Freer elevator is placed beneath the full-thickness flap to the level of the third tarsometatarsal joint, and the lateral incision is made overlying the lateral border.
- Dissection extends through the overlying extensor retinaculum, exposing the extensor digitorum communis tendon and medial margin of the extensor digitorum brevis muscle, both of which are retracted laterally (TECH FIG 2).
  - Care is taken not to violate the adjacent neurovascular bundle, which is maintained within its soft tissue envelope.
- The underlying third tarsometatarsal joint capsule is identified and a full-thickness subperiosteal flap is developed extending medially toward the lateral portion of the second tarsometatarsal joint, and laterally toward the fourth and fifth tarsometatarsal joints where necessary.
- Again, the status is noted of each of the tarsometatarsal and intercuneiform joint capsules dorsally, and therefore the extent of instability of each joint.
ARTICULAR SURFACE ASSESSMENT AND DECISION MAKING

- The fracture lines and articular surface of the involved joints are then débrided of residual hematoma and assessed for chondral damage.
- If more than 50% of the articular surface of the medial and middle column joints is involved, primary arthrodesis should be considered, although this is controversial.
- Arthrodesis of the fourth and fifth tarsometatarsal joints should be avoided if possible.
- If primary arthrodesis is elected, the involved joints are meticulously débrided of residual articular cartilage, preserving the underlying subchondral plate.
- The joints are irrigated and the subchondral plate is perforated with a 2.0-mm drill bit to stimulate vascular ingrowth.
- Supplemental allograft mixed with highly concentrated platelet aspirate is then placed within the involved joint spaces.

PROVISIONAL REDUCTION AND DEFINITIVE STABILIZATION

First Tarsometatarsal Joint

- The provisional reduction begins medially at the first tarsometatarsal joint if injured. Although the exact reduction maneuver may vary depending on the injury pattern, the first metatarsal is typically supinated (externally rotated) relative to the medial cuneiform.
- Correction of this rotational deformity is crucial in restoring the medial column and the weight-bearing function of the first ray. The reduction of the remaining midfoot joints depends on an anatomic reduction of the first tarsometatarsal joint.
- The provisional reduction is held with a 2.0-mm Kirschner wire and confirmed under fluoroscopy (TECH FIG 3A).
- Definitive stabilization is then obtained at the first tarsometatarsal joint with 3.5-mm solid cortical position screws (TECH FIG 3B–D).
- The first screw is placed from distal to proximal, starting at the dorsal crest and distal to the metaphyseal–diaphyseal junction, and is angled toward the plantar–proximal cortex of the medial cuneiform; this screw is generally 45 to 50 mm long.
- A second screw is placed from proximal to distal starting at the edge of the naviculocuneiform joint, and similarly angled to exit at the plantar cortex distal to the metaphyseal–diaphyseal junction. This screw typically measures 40 to 45 mm.
- In a primary arthrodesis, these screws are placed in lag fashion.
- For larger patients, 4.0-mm cortical screws may be used for further stability.

![TECH FIG 3](image-url) - Reduction and stabilization of first tarsometatarsal joint. A. Provisional reduction. B. Distal-to-proximal screw. C. Proximal-to-distal screw. D. Long bicortical trajectory of screws for enhanced stability.
Lisfranc Joint

- A pointed reduction forceps is then placed from the medial cuneiform to the lateral border of the second metatarsal to anatomically reduce the so-called Lisfranc joint; care is taken to ensure accurate dorsal-plantar alignment of the second tarsometatarsal joint.
- The reduction is confirmed under fluoroscopy, and a 2.0-mm Kirschner wire that mirrors the intended path of the screw is placed to provide further rotational control (TECH FIG 4A,B).
- There is typically a distinct cortical “shelf” on the medial cuneiform that provides an excellent buttress for screw purchase.
  - A 3.5-mm cortical screw is placed through a stab incision overlying this cortical shelf medially, angling toward the proximal metaphysis of the second metatarsal; for a primary arthrodesis, this screw is placed in lag fashion (TECH FIG 4C).

Other Joints

- If the intercuneiform joint is involved, it is first reduced and stabilized before stabilizing the Lisfranc joint (TECH FIG 5A). Alternatively, this joint may also be reduced and stabilized before stabilizing the first tarsometatarsal joint.
  - A 3.5-mm cortical screw is again used, coursing parallel to the plane of the naviculocuneiform joint. It is placed in lag fashion for a primary arthrodesis.
  - Care is taken not to violate the articulation between the middle and lateral cuneiform.
The second tarsometatarsal joint is then provisionally reduced and provisionally stabilized with a 1.6-mm Kirschner wire.

Definitive fixation is obtained with a countersunk 2.7-mm cortical screw from distal to proximal; it is placed in lag fashion for a primary arthrodesis (TECH FIG 5B).

The third tarsometatarsal joint is reduced and stabilized in identical fashion (TECH FIG 5C).

For a metatarsal base fracture or fracture-dislocation pattern precluding transarticular fixation, bridge plate fixation may be required.

We prefer a low-profile (2.0 or 2.4 mm) reconstruction plate and 2.4-mm cortical screws (TECH FIG 6).

The fourth and fifth tarsometatarsal joints are then reduced and definitively stabilized with 1.6-mm Kirschner wires.

Because the intermetatarsal ligaments between the third, fourth, and fifth metatarsals are often preserved, these joints may anatomically reduce indirectly, thereby allowing percutaneous stabilization.

The Kirschner wires are contoured and buried beneath the skin layer through separate stab incisions, which facilitates removal at 6 weeks postoperatively, either in the office under local anesthesia or in the operating room under sedation (TECH FIG 7).

For a cuboid fracture, the cuboid is reduced and definitively stabilized to ensure restoration of lateral column length before stabilizing the fourth and fifth tarsometatarsal joints; by definition, this is then an open reduction (TECH FIG 8A).

Final fluoroscopic images are obtained, confirming articular reduction and implant placement (TECH FIG 8B).
PART 2 PELVIS AND LOWER EXTREMITY TRAUMA • SECTION IV FOOT AND ANKLE

POSTOPERATIVE CARE

- The patient is converted to a venous compression stocking and prefabricated fracture boot, and early progression to motion is initiated.
  - The Kirschner wires traversing the lateral column joints are removed 6 weeks postoperatively.
  - Weight bearing is not permitted until 10 to 12 weeks postoperatively, at which point weight-bearing radiographs are obtained to confirm maintenance of reduction.
  - The patient is gradually allowed to resume regular shoes, and activity is advanced as tolerated thereafter.
  - In a primary arthrodesis, the limb is immobilized in serial short-leg non-weight-bearing casts for 10 to 12 weeks after surgery, at which point radiographic union is confirmed on weight-bearing radiographs.
  - The patient is then converted to a venous compression stocking and prefabricated fracture boot, and weight bearing is advanced as described previously.

OUTCOMES

- Outcomes after open reduction and internal fixation of Lisfranc injuries are generally good overall, as patients have relatively few activity limitations. An accurate diagnosis and anatomic reduction are crucial to ensuring satisfactory results.†
- Outcomes for pure ligamentous patterns are less predictable after open reduction and internal fixation; these patients tend to have higher rates of posttraumatic arthritis.† Primary arthrodesis appears to be especially beneficial in this situation: one recent study reported a greater than 90% return to preinjury level after primary arthrodesis.†
- Late arthrodesis as salvage for posttraumatic arthritis provides predictable pain relief and functional improvement.†,9

PEAKLS AND PITFALLS

<table>
<thead>
<tr>
<th>Misdiagnosis of proximal joint injuries (medial, middle, or lateral cuneiform; intercuneiform joint; cuboid fracture)</th>
<th>Because of the highly variable injury patterns, a high index of suspicion must be maintained. Injury radiographs must be closely scrutinized preoperatively for proximal joint involvement. If radiographs are inconclusive, CT evaluation is warranted. During surgery, the status is noted of each of the intercuneiform joint capsules dorsally, and therefore the extent of instability of each joint.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Correcting plantar displacement or malalignment of the first and second tarsometatarsal joints</td>
<td>Strict attention is paid to dorsal–plantar alignment of the first and second metatarsals and their respective cuneiforms, because plantar displacement or malalignment greater than 2 mm may affect the weight-bearing metatarsal cascade, potentially resulting in a transfer (metatarsalgia) lesion.</td>
</tr>
<tr>
<td>Correcting supination malrotation of first tarsometatarsal joint</td>
<td>There is typically a distinct dorsal crest on both the first metatarsal and medial cuneiform. They should be precisely aligned to ensure an accurate reduction.</td>
</tr>
<tr>
<td>Definitive fixation of first tarsometatarsal joint</td>
<td>Because of the hard cortical bone at the diaphysis of the first metatarsal, the screwhead of the distal-to-proximal screw is specifically countersunk to avoid compromise of the dorsal cortex and loss of fixation.</td>
</tr>
<tr>
<td>Definitive fixation of Lisfranc joint</td>
<td>With fixation of the Lisfranc joint, the screw must angle slightly dorsally (relative to the plantar foot) to accommodate the normal “Roman arch” configuration in the coronal plane.</td>
</tr>
</tbody>
</table>

We do not routinely remove hardware unless symptomatic or specifically requested by the patient, in which case the implants may be removed at 1 year after surgery.
Chapter 22  ORIF OF LISFRANC INJURY

COMPLICATIONS
- Delayed wound healing, wound dehiscence, deep infection
- Malunion or nonunion
- Late displacement (premature implant removal)
- Neurovascular compromise
- Chronic pain

REFERENCES
DEFINITION
- A Jones fracture represents an acute injury at the metaphyseal-diaphyseal junction of the fifth metatarsal. The fracture should not have extension distal to the fourth-fifth intermetatarsal articulation (FIG 1).
- This fracture is often seen as a result of sporting or athletic activities.
- The fracture begins on the lateral aspect of the fifth metatarsal and may propagate into the metatarsocuboid joint.
- Three subsets of the fracture exist, as described by Torg (FIG 2):
  - Type 1: Acute fracture where the fracture line has sharp margins and no intramedullary sclerosis. Often involves only the lateral cortex.
  - Type 2: Delayed union where fracture line involves both cortices with associated periosteal bone formation, widening of the fracture line, and evidence of intramedullary sclerosis.
  - Type 3: Nonunion demonstrated by bone resorption with radiolucency at the fracture line and obliteration of the medullary canal by sclerotic bone

ANATOMY
- There are two major motor insertions onto the fifth metatarsal:
  - The peroneus brevis inserts onto the dorsal aspect of the fifth metatarsal tubercle.
  - The peroneus tertius inserts onto the dorsal aspect of the metatarsal at the metaphyseal–diaphyseal junction.
- The plantar fascia has a strong insertion along the plantar aspect of the fifth metatarsal.
- The shaft is supplied by a single nutrient artery that enters from the medial cortex at the junction of the proximal and middle thirds of the diaphysis. The base and tuberosity are supplied by secondary epiphyseal and metaphyseal arteries (FIG 3).

PATHOGENESIS
- Acute Jones fractures are the result of plantarflexion at the ankle and adduction of the forefoot.
- Tensile forces along the lateral border of the metatarsal result in a transverse fracture.
- They are typically the result of sporting or athletic events, with many instances described in football and basketball players.
- This should not be confused with a diaphyseal stress fracture, where the athlete describes prodromal symptoms that have existed for weeks to months. Radiographic assessment of this type will demonstrate signs of a stress reaction.

NATURAL HISTORY
- The Jones fracture was originally described in 1902 by Sir Robert Jones, who described a transverse fracture at the metaphyseal-diaphyseal junction in four individuals, including himself.
- The natural history and outcomes of nonoperative and operative treatment are difficult to determine because many published reports include a mixture of acute Jones fractures and diaphyseal stress fractures.
- Various studies have examined nonoperative versus operative treatment.
- Operative treatments have included internal fixation with or without bone grafting and bone grafting alone.
- Nonoperative treatment of the acute fracture is associated with an increased risk of delayed or nonunion due to the watershed blood supply at the metaphyseal–diaphyseal junction in the metatarsal.

PATIENT HISTORY AND PHYSICAL FINDINGS
- The patient may describe participation in an athletic event where, after a particular maneuver, there is an acute onset of pain over the lateral border of the foot.
- The patient may have swelling and ecchymosis over the lateral border of the foot.
- Pain will be elicited with direct palpation over the base of the fifth metatarsal.
- Physical examination should include:
  - Direct palpation over the base of the fifth metatarsal: Pain in this region increases suspicion of injury.
  - Direct palpation over the tarsometatarsal joint complex: Pain indicates possible injury to the Lisfranc complex.
  - Passive dorsiflexion–plantarflexion of individual metatarsal heads: Pain indicates possible injury to the Lisfranc complex.
  - Attempted single-limb heel lift: Pain indicates possible injury to the Lisfranc complex.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- Radiographs of the affected foot, including anteroposterior, lateral, and oblique, are sufficient to diagnose an acute Jones fracture.
- Weight-bearing radiographs of the affected foot are obtained to rule out a Lisfranc injury.

DIFFERENTIAL DIAGNOSIS
- Diaphyseal stress fracture
- Avulsion fracture of the base of the fifth metatarsal
- Lisfranc sprain or subluxation
- Cuboid fracture

NONOPERATIVE MANAGEMENT
- Non-weight bearing in a short-leg cast for 6 weeks, followed by weight bearing in a walker boot for an additional 6 weeks
Torg’s series of 15 patients demonstrated a 93% union rate at an average of 6.5 weeks.\(^{14}\)

Clapper reported union in 72% of acute Jones fractures treated with a non-weight-bearing short-leg cast for 8 weeks followed by weight bearing in a cast or walker boot.\(^{1}\)

**SURGICAL MANAGEMENT**

- The indications for surgical fixation of an acute Jones fractures have not been clearly defined.

- High-performance athletes or individuals desiring a quicker return to activity may benefit from intramedullary screw fixation, as this provides a more predictable and shorter recovery period.

---

**Preoperative Planning**

- If percutaneous screw fixation of the fifth metatarsal is planned, preoperative measurement of the intramedullary canal will ensure that the proper hardware is available.

**Positioning**

- The patient should be placed in the supine position on a radiolucent table.

- A bolster should be placed under the ipsilateral buttock to increase the exposure to the lateral aspect of the foot.

- A C-arm image intensifier is used to assist in the operative procedure. It is helpful to have the entire limb draped free so that the knee may be flexed past 90 degrees. This will also facilitate imaging of the foot (FIG 4).

---

**FIG 1** • Acute Jones fracture. The fracture line is at the junction of Zones 1 and 2; there is no cortical hypertrophy or periosteal reaction.

**FIG 2** • Torg type II diaphyseal stress fracture. Widening of the fracture line and periosteal bone formation are shown.
A tourniquet is not required but may be chosen based on surgeon preference.

**Approach**
- A dorsolateral approach to the base of the fifth metatarsal is preferred.

### PERCUPTANEOUS INTRAMEDULLARY SCREW FIXATION

**Incision and Dissection**
- A 2- to 3-cm incision is made parallel to the plantar surface of the foot.
- The incision should begin 2 cm proximal to the tip of the fifth metatarsal tuberosity. The location should be confirmed with a C-arm image (TECH FIG 1).
- Blunt dissection is used to expose the tuberosity.

**Screw Portal Creation and Guidewire Placement**
- With a drill guide used to protect the soft tissues, a 2.5-mm drill is used to open the entry portal for the screw.
  - The correct entry site is one that is in line with the medullary canal just medial to the tip of the tuberosity (TECH FIG 2A).

**Screw Placement**
- The surgeon reams the intramedullary canal with a 3.2-mm cannulated drill, leaving the drill sleeve in place to protect soft tissues (TECH FIG 3A,B).
  - The drill should be passed distal to the fracture site.
  - The proximal end is then reamed with a 4.5-mm drill. This facilitates countersinking the screw to avoid soft tissue irritation.
  - The surgeon uses the guidewire to measure the proper length of the screw required (TECH FIG 3C).
  - The surgeon places an appropriately sized 4.5-mm, partially threaded AO screw with a small profile head into the intramedullary canal (TECH FIG 3D,E).
  - In larger individuals, a 6.5-mm screw may be substituted, using the appropriately sized drills to create the starting portal and to overream the proximal cortex.
TECH FIG 2 • **A.** Creation of the starting portal with a 2.5-mm drill bit and drill guide. **B.** Fluoroscopic confirmation of entry placement. **C.** Insertion of a flexible guidewire down the intramedullary canal. **D,E.** Fluoroscopic confirmation of guidewire placement.

TECH FIG 3 • **A.** Preparation of the intramedullary canal with a 3.2-mm cannulated drill and protective drill sleeves. **B.** Fluoroscopic view. **C.** Measurement of the correct screw length. **D,E.** Final radiographs.
INLAY BONE GRAFTING WITHOUT INTERNAL FIXATION

- The technique is similar to the Russe technique for scaphoid nonunion.\textsuperscript{11,14}
- The base of the fifth metatarsal is approached through a curvilinear dorsolateral incision (TECH FIG 4A).
- The fracture site is exposed subperiosteally and a rectangular section of bone measuring 0.7 \times 2.0 cm centered over the fracture is outlined by four drill holes.
- A sharp osteotome is used to remove the outlined section of bone (TECH FIG 4B).
- The medullary canal is then curetted, drilled, or both until all of the sclerotic bone has been removed and the canal has been re-established.
- An autogenous corticocancellous bone graft with the same measurements as the removed fragment is then removed from the anteromedial aspect of the distal end of the tibia.
- The graft should be contoured so that the cortical portion of the graft fits accurately into the rectangular defect and does not obstruct the medullary canal (TECH FIG 4C).
- The periosteum, subcutaneous tissue, and skin are then closed.
- To avoid a stress riser, the bone removed from the fifth metatarsal is placed into the tibia defect before wound closure.
- The patient is then immobilized in a non-weight-bearing cast.

TECH FIG 4 • A. Curvilinear incision over dorsolateral aspect of foot. B. The fracture site is exposed and a rectangular area is outlined in the bone using drill holes. C. The graft is shaped and placed into the defect created.

PERCUTANEOUS INTRAMEDULLARY SCREW FIXATION WITH LOCAL BONE GRAFT

- The procedure is performed as described for percutaneous intramedullary screw fixation.\textsuperscript{8}
- Once the medullary canal has been overdrilled over the guidewire, the wire is removed.
- A slender curette is advanced to the depth of the fracture and manipulated to add a mass of cancellous bone to the fracture site.
- Care should be taken to limit procurement of bone to within 7 mm of the fracture site.
- Once the local bone grafting has been completed, the wire is reintroduced into the canal.
- The intramedullary screw is placed as described for percutaneous intramedullary screw fixation.
PEARLS AND PITFALLS

Failure of hardware • A 4.5-mm screw or larger is used when possible.

Failure of hardware • Touch-down weight bearing in a walker boot is used for 6 to 8 weeks. Weight bearing is advanced only when radiographic evidence of fracture healing is observed.

POSTOPERATIVE CARE

• Immediately after surgery, the patient should be immobilized in a walker boot and should be limited to touch-down weight bearing for 6 to 8 weeks.
• During this period, range of motion and gentle strengthening may be allowed.
• After 6 to 8 weeks, weight bearing and boot removal are allowed when radiographic evidence of healing is observed.
• Return to full activity, especially competitive athletics, is allowed only when complete healing is observed on radiographs in three planes: anteroposterior, lateral, and oblique.
• Functional bracing or orthosis is recommended for individuals returning to athletic activities.

OUTCOMES

• Portland et al10 treated 15 patients with acute Jones fracture or Torg type I fracture and achieved 100% union at an average of 6.25 weeks.
• DeLee et al3 reported 100% success in acute Jones fractures treated with percutaneous intramedullary screw fixation. No complications were reported.
• Mindrebo et al9 treated nine patients with acute Jones fractures with outpatient intramedullary screw fixation and had 100% union at an average of 6 weeks. One patient had the screw removed because of theoretical concerns over screw breakage.

COMPLICATIONS

• Refractures and nonunions may occur when small-diameter screws are used. Screws less than 4.5 mm have been shown biomechanically to be weaker than larger screws. Using the largest-diameter screw where all of the screw threads cross the fracture site has been demonstrated to provide the best biomechanical fixation.
• Refractures and nonunions may occur when the patient returns to early weight bearing and when the Jones fracture is fixed in elite-level competitive athletes who may push themselves to return to activities before union has occurred.

Osteonecrosis may also be idiopathic.

For the past 40 years, cemented total hip arthroplasty (THA) has been the most successful surgical solution for end-stage hip disease.

Cemented THA is appropriate for treatment of hip pathology caused by a variety of degenerative, inflammatory, traumatic, vascular, developmental, and metabolic disorders.

ANATOMY

The hip is a diarthrodial synovial joint, consisting of the articulation of the femoral head with the acetabulum. It functions as a ball-and-socket joint, with inherent bony constraints that define the range of motion. The laxity or tightness of the associated soft tissue also affects kinematics and function.

The acetabulum develops at the junction between three embryologically distinct bones—the ilium, ischium, and pubis—which fuse at the triradiate cartilage during adolescence.

The acetabulum typically demonstrates 15 to 20 degrees of anteverision, as does the femoral neck. Normal combined anteverision is therefore 30 to 40 degrees, although the degree of anteverision varies considerably between individuals.

PATHOGENESIS

Degenerative joint disease (DJD) constitutes a final common pathway for various hip disorders of distinct etiologies.

Developmental abnormalities of the hip can lead to femoroacetabular impingement, abnormal joint reaction forces and articular shear forces, and consequent mechanical joint degeneration. These abnormalities include:
- Developmental dysplasia
- Coxa profunda
- Protrusio acetabuli
- Acetabular retroversion
- Pistol-grip deformity of the proximal femur
- Legg-Calvé-Perthes disease
- Slipped capital femoral epiphysis
- Posttraumatic arthritis can develop after fractures of the femoral head, femoral neck, or acetabulum.
- Osteoarthritis may also be idiopathic.
- Rheumatologic conditions such as rheumatoid arthritis and the seronegative spondyloarthropathies are caused by autoimmunity.
- Osteonecrosis of the femoral head can result from many etiologic factors:
  - Alcoholism
  - Corticosteroid use
  - Chemotherapy
  - Sickle cell disease
  - Systemic lupus erythematosus
  - Vasculitis
  - Human immunodeficiency virus infection
  - Coagulopathy

Cemented THA is appropriate for treatment of hip pathologies caused by a variety of degenerative, inflammatory, traumatic, vascular, developmental, and metabolic disorders.

NATURAL HISTORY

The natural history of degenerative joint disease is progression of disease. Although clinical symptoms may wax and wane, they generally become more severe, more frequent, and more debilitating over time.

Although medications can help control the progression of rheumatoid arthritis and other inflammatory conditions, no medical therapies currently have been proved to act as disease-modifying agents in degenerative joint disease.

When osteoarthritis is a consequence of anatomic abnormalities, there is hope that surgical correction of these abnormalities may unload the joint, halt progression of disease, and even allow for biologic repair.

Periacetabular osteotomy may positively impact the natural history of joint degeneration in acetabular dysplasia, but the long-term effect of osteotomy on hip function and progression of arthrosis is unknown. In the presence of moderate DJD, progression of disease commonly occurs in spite of a well-performed osteotomy.

Similarly, osteochondroplasty of the femoral neck and acetabular rim may relieve symptoms associated with femoroacetabular impingement, but it is not known whether these procedures will reduce the progression of arthrosis.

PATIENT HISTORY AND PHYSICAL FINDINGS

Initial evaluation should focus on identifying the extent to which hip pain can be attributed to intra-articular hip pathology. Hip pain may be referred to the groin, the peritrochanteric region, the thigh, the knee, or, occasionally, below the knee. Lumbar spine disease may also cause pain in these regions.

Although the source of the pain usually can be identified on the basis of physical examination, occasionally selective anesthetic injection is necessary to elucidate the relative contributions of overlapping pathologies to a patient’s symptoms.

Palpation is performed to assess for areas of tenderness, warmth, fluctuance, or mass.

Trochanteric bursitis is a common cause of hip area pain that can be ruled out by identifying a nontender bursa.

An inguinal mass may suggest that groin pain is related to a hernia.

Active and passive range of motion should be assessed.

Flexion contracture commonly is encountered, as are limited internal rotation and abduction.

Limited external rotation, if present, impairs activities of daily living.
DIFFERENTIAL DIAGNOSIS
- Lumbar spine pathology
- Spinal stenosis and neurogenic claudication
- Herniated nucleus pulposus
- Degenerative disc disease or spondylitis
- Sacroiliac joint pathology
- Trochanteric bursitis
- Tendinopathy of the gluteus medius or minimus
- Iliopsoas bursitis
- Inguinal hernia
- Vascular claudication

NONOPERATIVE MANAGEMENT
- Options include weight loss, activity modification, physical therapy, injections, pain management, and the use of walking aids. These interventions do not alter the underlying disease process, but they may substantially diminish pain and disability.

SURGICAL MANAGEMENT
- Cemented THA has been a highly successful operation. Significant early complications are uncommon, and patient outcomes are outstanding in the short and intermediate term. Long-term outcomes beyond 10 to 15 years are limited by component wear, fixation failure, and biologic reaction to wear debris.
- In most reported series, fixation has been the limiting factor for the survival of hip implants in patients with long life expectancies.
- The durability of cement fixation is highly dependent on meticulous surgical technique. Bone cement is vulnerable to failure under tension and shear, which can be caused by gaps in the cement mantle. Stress risers place cement at high risk of fracture.
- Improvements in cement technique have resulted in a reduction in the rates of aseptic loosening of femoral components.
- Acetabular cement fixation remains challenging for many surgeons, with variable results over the long term. The appearance of the bone–cement interface on the immediate postoperative radiograph can predict the durability of cemented acetabular fixation.
- This supports our contention that a surgeon who is able to achieve good cement technique consistently can expect reproducible long-term results.

Preoperative Planning
Indications
- Reproducible, durable, long-term outcomes using cement fixation have been achieved in older, lighter patients, particularly women, with low to moderate activity levels and relatively normal anatomy of the pelvis and proximal femur. If THA is indicated for such a patient, cement fixation remains an excellent option for both components.
- When distorted femoral anatomy precludes the use of standard press-fit prostheses, cement fixation may be the best or only option.
- Cement fixation may also be the best option in pathologic bone associated with tumor or radiation, or in any other situation in which bone in- or ongrowth cannot be anticipated.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- Plain radiographs should be obtained, as weight-bearing films if possible.
- Low anteroposterior (AP) view of the pelvis centered over the pubic symphysis and including the proximal third of the femora. Slight internal rotation of the hips allows accurate assessment of the neck shaft angle. The coccyx should be pointing directly to the symphysis pubis and located about 3 cm above the symphysis pubis if pelvic rotation is not present.
- AP and false-profile views of the involved hip.
- AP and lateral lumbar spine, lateral lumbosacral spine
- CT, MRI, and other supplemental studies rarely are needed.
Implant Selection

- Choice of prosthesis should be based on critical review of the published outcomes and the surgeon’s familiarity with an implant. This includes design features and rationale, instrumentation, and potential technical pitfalls.
- It is generally agreed that the optimal cemented acetabular component is all polyethylene (Fig 1), with multiple pegs to ensure concentric insertion within a cement mantle of appropriate thickness, and a peripheral flange to optimize pressurization of cement during component insertion. Recent data challenge the value of polyethylene pegs, demonstrating an association with radiographic evidence of loosening.10
- On the femoral side, there is some debate as to whether the optimal prosthesis is roughened to allow interdigitation of cement and rigid fixation at the cement–prosthesis interface, or polished and tapered to allow slight subsidence into a stable position without generating wear particles.
- Both design philosophies have resulted in good to excellent long-term results when properly employed.12,16
- Conversely, simply roughening the surface of a successful smooth stem has led to a surprising number of early failures of fixation.12
- The consensus seems to be that either philosophy can work if it is applied consistently in all aspects of component design, but that “mixing and matching” elements from the two design philosophies gives unpredictable results.

Templating

- Once the implant system has been chosen, templates can be compared to patient radiographs to predict implant size and determine the implant placement that will best reconstruct the patient’s center of rotation, offset, and leg length.
- A horizontal reference line is drawn between the inferior tips of the acetabular teardrops (Fig 2A). Both lesser trochanters are marked at their medial points (the medial tip of the lesser trochanter is the most reproducible landmark on the proximal femur radiographically). The perpendicular distance between the inter-teardrop line and the medial point of the lesser trochanter is measured for each hip (represented by the solid vertical lines in Fig 2A).
- The leg-length discrepancy is calculated by subtracting the value measured for the nonoperative hip from the value obtained for the operative hip.
- The centers of the femoral heads are marked—these are also the centers of rotation of the hip joints. A mark is also placed...
on the superior aspect of the lesser trochanter on the operative hip (this can be identified intraoperatively). The distance between the superior aspect of the lesser trochanter and the center of the femoral head (represented by the dashed lines in Fig 2A) is measured and recorded for each hip; this lesser trochanter-to-center distance is referred to as the LTC.

- Selection of the appropriate acetabular component requires a measurement of acetabular size. Cemented socket templating accounts for a 2-mm cement mantle in approximating the reamed hemispherical cavity. Implant size is estimated most accurately on the false-profile radiograph (FIG 2B).
- The acetabular template is positioned on the AP radiograph in 40 to 45 degrees of abduction,17,24 with its inferomedial border placed approximately 10 mm lateral to the teardrop (FIG 2C). The prosthesis should remain at or lateral to the medi- al floor of the acetabulum, and the superolateral corner of the component should fall near the superolateral border of the acetabulum.
- Slightly incomplete coverage of the acetabular component (up to 20%) may be acceptable.
- Once the desired position of the acetabular component is selected, the new center of rotation of the hip can be determined using the template. In most cases, the goal is to recreate the normal anatomic center of rotation, although changing the center of rotation by up to 10 mm may be accepted for the sake of optimal component fixation. Such a change may be necessary in cases of dysplasia with a high hip center.
- Attention then is turned to templating the femoral component. The goal is to choose an implant that permits an adequate cement mantle without excessive removal of cancellous bone, and restores anatomic leg length and offset.
- The template is placed in neutral position in the femoral canal. Its proximal–distal position should be selected on the basis of the bony constraints, the desire for a circumferential 2-mm cement mantle, and the goal of restoring leg length (FIG 2D).
- Most implant systems are available with standard or enhanced offset necks; the implant that optimizes the patient’s offset in relation to the new center of rotation of the socket is chosen.

- Modular femoral heads with the option of plus and minus sizes allow the surgeon to lengthen or shorten the femoral neck, affecting both leg length and offset.
- Once the optimal component position is selected, the level of the femoral neck cut is marked, and the distance from the lesser trochanter is recorded.
- After marking socket and femoral component positions on the radiograph, the vertical distance between the center of the acetabular component and the center of the femoral head will approximate the leg-length correction (FIG 2E).
- We seek an increase in leg length of 2 to 5 mm in most cases.22

### Positioning

- Positioning of the patient depends on choice of surgical exposure. For the posterolateral approach to the hip, we use the lateral decubitus position on a specially designed table.
- An axillary roll is used to prevent injury to the brachial plexus, and all bony prominences are carefully padded to avoid pressure-related complications.
- Many surgeons attempt to establish a fixed relationship between the pelvis and the floor to allow positioning of the acetabular component in reference to the plane of the floor.
- The use of internal landmarks may be more reproducible and also permits the surgeon more freedom in positioning.
- We prefer to tilt the table toward the surgeon during acetabular preparation and component insertion, optimizing visualization. A backrest is used to stabilize the patient during this maneuver.

### Approach

- Multiple surgical approaches can adequately expose the hip joint for THA.
- The posterolateral approach is desirable for its excellent, ex tensile exposure and avoidance of trauma to the abductor mechanism.
- With modern techniques of posterior soft tissue repair and implant positioning that restores the center of rotation, offset, leg length, and combined anteversion,2 dislocation rates are comparable to those observed with other approaches.20

---

### EXPOSURE

- A gently curved skin incision is made starting posterior and slightly proximal to the tip of the greater trochanter, passing about 1 cm posterior to the most prominent point of the greater trochanter on the lateral aspect of the femur, and distally along the shaft of the femur to approximately the level of the gluteus maximus insertion.
- The iliotibial band is incised slightly anterior to the line of the skin incision so that the fascial incision passes directly over the most prominent point of the trochanter and remains 5 to 10 mm anterior to the insertion of the gluteus maximus tendon into the proximal femur.
- The gluteus maximus muscle is encountered in the proximal portion of the fascial incision, and divided in line with its fibers.
- Partial or complete release of the gluteus maximus insertion into the linea aspera can be performed at this time.

This seldom is necessary for exposure, but may reduce the small risk of postoperative sciatic nerve palsy.14

- Release of the quadratus femoris off the posterior femur is performed with the electrocautery. This step is complete when the lesser trochanter is well exposed.
- The first perforator off the profunda femoris artery is often encountered during this step. It is easily cauterized before it is transected, but hemostasis can be more difficult if it is transected before it is recognized.
- The gluteus medius is then retracted anteriorly and proximally so that an incision may be made along the superior border of the piriformis tendon all the way down through the hip capsule.
- The sciatic nerve should be palpated and protected with the surgeon’s finger.
Intraoperative Assessment of Leg Length

- Prior to dislocation of the hip, a Steinmann pin is placed into the obturator foramen at the level of the infracotyloid groove. This landmark can be reproducibly identified by passing the pin just distal to the ischium at the level of the acetabulum.
- The surgeon should appreciate a pop as the pin pierces the obturator membrane, at which point the pin should be inserted no further.
- The femur is placed in neutral position on the operating table, and the position of the vertical Steinmann pin is marked on the femur using the electrocautery and a marking pen (TECH FIG 1).
- The Steinmann pin can be replaced later in the case, and the mark on the femur provides a reference for assessment of change in leg length.

Dislocation of Hip and Osteotomy of Femoral Neck

- The hip is dislocated posteriorly using gentle flexion, adduction, and internal rotation.
- The center of the femoral head is then estimated and marked, and the distance from the center to the highest point of the lesser trochanter (LTC) is measured and recorded (TECH FIG 2).
- Reconstruction of the anatomic geometry of the hip, including leg length and offset, is aided by approximate reproduction of this distance.
- In general, a slight increase in the LTC will optimize hip stability without overlengthening the leg or overstretching the iliotibial band.
- The femoral neck cut is made perpendicular to the inferior surface of the neck, aiming at the junction of the femoral neck with the greater trochanter. The cut neck should be left a few millimeters longer than predicted on preoperative templating, to allow for measurement error and imprecision in templating.
- Additional bone can be removed easily after femoral preparation using either the sagittal saw or the calcar planar.

Acetabular Exposure

- Wide exposure of the acetabulum is achieved by translating the femur anteriorly. This often requires release of the anterosuperior capsule, with or without release of the reflected head of the rectus femoris muscle, depending on the underlying ligamentous laxity.
- Release of the tendinous insertion of the gluteus maximus into the linea aspera allows further anterior translation.
- The labrum should be resected in its entirety; the transverse acetabular ligament should be preserved to provide a landmark for the placement of the inferior portion of the acetabular component and a restraint to the extrusion of cement inferiorly during cement pressurization and component insertion.
- The pulvinar should be removed from the fovea using the electrocautery to allow visualization of the medial wall of the acetabulum.
ACETABULAR PREPARATION

- A slightly undersized reamer is used initially to ensure appropriate medialization without penetrating the medial wall, followed by sequential concentric reaming until the blush of cancellous bone is seen in the pubis anteriorly and the ischium posteriorly.
- Most of the strong subchondral bone of the ilium in the superior aspect of the acetabulum should be preserved to provide support for the prosthesis. However, sclerotic bone must be penetrated sufficiently to permit cement interdigitation using multiple holes with a high-speed burr.
- Alternatively, a recent randomized, controlled clinical trial demonstrated significantly improved radiographic appearance of the cement mantle with careful removal of most of the subchondral bone to allow cement interdigitation into cancellous bone of the roof of the acetabulum.\(^\text{11}\)
- The appropriate position for the acetabular component is selected using a trial prosthesis. Insertion of the trial component should be easy and free of bone or soft tissue obstruction to allow for unencumbered insertion of the actual component. If the margins of the acetabular cavity remain tight, it can be reamed up by 1 mm at the periphery.
- Internal landmarks used for positioning the acetabular cup include the anterior wall and pubic ramus, the posterior wall, the transverse acetabular ligament, and the superior acetabular rim.
- With normal acetabular morphology, positioning the prosthesis just within the confines of the acetabulum ensures appropriate component abduction of 40 to 45 degrees and anteversion of 10 to 20 degrees.
- In cases with large anterior osteophytes or preoperative acetabular retroversion, as noted by a positive crossover sign, the posterior wall and the transverse acetabular ligament are used preferentially to guage proper anteversion. Anterior osteophytes should be debulked using a burr or an osteotome; this reduces the risk of anterior bony impingement with hip flexion and internal rotation.
- Once the appropriate component position is selected using the trial, it can be marked on the bone using methylene blue, and the relationship of the component to the aforementioned landmarks can be noted visually to assist in placement of the final component (TECH FIG 3A).
- A high-speed burr is then used to create holes in the pubis, ischium, and ilium for cement intrusion and “macrolock” to complement the “microlock” achieved by interdigitation in bony trabeculae of cancellous bone.
- If acetabular cysts are present, these are débrided and the sclerotic margins removed using the burr.
- A dry operative field free of debris is necessary for maximal cement interdigitation into cancellous bone (TECH FIG 3B).
- This is achieved by the use of hypotensive regional anesthesia with mean arterial pressure in the range of 45 to 70 mm Hg, and pulse-irrigation to remove fat and blood followed by drying with a sponge, with or without local use of epinephrine.
- Although it is not our practice, a recent study demonstrated improved cement intrusion when suction aspiration of the ilium was performed at the time of cementing to help maintain a dry bone surface.\(^\text{13}\)

CEMENTING THE ACETABULAR COMPONENT

- Cement should be doughy but still relatively low in viscosity when it is placed in the acetabulum. Uniform simultaneous cement pressurization then is achieved using a rubber balloon that is pressed into the acetabulum (TECH FIG 4A).
- After pressurization has been maintained for 30 to 60 seconds, the balloon is removed, and the transverse acetabular ligament is cleared of cement (TECH FIG 4B). This minimizes intra-pelvic extrusion and allows visualization of the floor of the acetabulum to guide placement of the acetabular component.
- The acetabular component is then inserted, with care to match the abduction and anteversion selected at the time the trial prosthesis was inserted. The component should have an outer diameter 2 mm smaller than that of the final reamer, allowing for an adequate cement mantle.
- Extra cement is removed while pressure is maintained on the acetabular component using a Charnley pusher centrally to minimize angular forces on the cement mantle until the cement has hardened.
FEMORAL PREPARATION

- Exposure requires proper delivery of the proximal femur out of the wound by flexion, adduction, and internal rotation. Difficulty achieving this position may be remedied by release of the gluteus maximus tendon.
- The starting point for entry into the femoral canal is in the posterior lateral femoral neck. This allows cylindrical reamers and straight broaches to be inserted along the anatomic axis of the proximal femoral diaphysis while maintaining a uniform cement mantle despite the proximal femoral bow.
  - To achieve the appropriate starting point, all residual soft tissue must be removed from the posterior lateral femoral neck, and remaining bone must be removed using a high-speed burr or other tool.
  - Many surgeons successfully use a box osteotome to achieve this goal, although it does not have the precision of the burr (TECH FIG 5).
  - Once the starting point has been prepared, a conical canal-finding reamer is introduced to aid in the identification of the anatomic axis of the femur. The entry point into the femur is opened, while reaming of the diaphyseal endosteum is minimized. Broach preparation of the canal without extensive reaming preserves cancellous bone to permit optimal cement interdigitation.
  - Sequential broaching is then performed, with care to insert the broaches in appropriate anteversion. This is achieved by following the patient's native version, unless the patient has significant deformity of the proximal femur or the acetabular component is known to be in excessive anteversion or retroversion.
  - The degree of anteversion is best assessed visually if the assistant holds the tibia perpendicular to the plane of the floor.
  - Sequential broaching is continued until torsional stability is achieved at a depth of broach insertion that brings the proximal surface of the broach into the plane of the neck cut.
  - If careful preoperative templating was performed, this should result in restoration of leg length and offset with the implant system being utilized. This can be confirmed following the attachment of trial necks and heads.
  - Many hip systems have options for standard or extended offset necks; these can be defined by the amount of offset or by the neck–shaft angle.
  - In general, the neck that best recreated the anatomic geometry on preoperative templating should be selected.
  - Be aware, however, that radiographs may underestimate offset if the hip is not internally rotated to bring the femoral neck perpendicular to the x-ray beam.

ASSESSMENT OF THE RECONSTRUCTION AND SOFT TISSUE BALANCE USING TRIAL COMPONENTS

- A trial reduction is then performed, and the adequacy of the reconstruction is assessed by four principal maneuvers:
  - First, the hip is internally rotated until the femoral head trial and acetabular component are coplanar (TECH FIG 6A,B) and the knee is bent 90 degrees.
  - If the coronal plane of the pelvis is perpendicular to the floor, the angle between the tibia and the floor is the combined anteversion of the femoral and acetabular components.15
Fourth, the hip is flexed and internally rotated, and the stability is assessed. The surgeon should feel a clear soft tissue resistance prior to dislocation, rather than a smooth unimpeded motion.

Some additional information may be gained from the Ober test, in which the knee is flexed 90 degrees and the hip is extended to neutral and abducted. The knee is then released, while the examiner continues to support the foot.

If the offset has been substantially increased, the knee will remain elevated (ie, the hip will remain abducted), indicating tightness of the iliotibial band.

Results of this test are meaningless unless compared to the preoperative findings, as some hips have a positive Ober test preoperatively.

A final test that provides more limited information is the “shuck” or “push-pull” test, in which an assistant applies traction on the femur with the hip reduced but internally rotated, and the surgeon subjectively assesses the extent to which the femoral head can be distracted from the acetabulum.

There should be some give with push-pull, but the assistant should be unable to completely dislocate the hip with simple traction.

Used in isolation, this test may lead the surgeon to over-lengthen the leg.

If the hip is found to be too loose, a plus-sized modular head can be used or the size of the femoral stem can be increased such that the stem sits more proudly within the femoral canal. Larger stems may also have longer necks, depending on the implant system.

If leg length is appropriate but offset is insufficient, the surgeon can switch from a standard to an extended-offset stem.

If the anterior capsule is found to be tight in a hip with an otherwise acceptable reconstruction, we advocate anterior capsulotomy to balance the hip.

If the hip is too tight—ie, with excessive anterior capsular tightness, a positive Ober test, and excessive leg-lengthening—the femoral trial can be downsized or implanted deeper into the femur, or the minus-sized femoral head can be selected.

We recommend against planning to use the minus-sized femoral head initially, because most implant systems have only a single minus size. Consequently, if the final reconstruction varies from the trial reconstruction, the surgeon is left without the option of further decreasing leg length and offset.

Combined anteversion of 35 to 45 degrees is optimal in women, whereas somewhat less anteversion is desirable in men, who usually have less lumbar lordosis.

Second, the hip is externally rotated with the hip and knee in extension. The anterior capsule should be loose enough to allow external rotation of the femur such that the greater trochanter approaches one fingerbreadth away from the ischium, but not so loose as to allow impingement of the trochanter against the ischium, or of the prosthetic neck against the posterior socket.

Third, the Steinmann pin is replaced in the obturator foramen at the level of the infracotyloid groove, and the relative lengthening or shortening of the leg is measured and noted.

In general, the goal is to increase the leg length by less than 5 mm to optimize hip stability without generating leg-length inequality. However this varies with preoperative clinical leg-length discrepancy and other factors.

The femoral trials are removed, and the femur is prepared for cement fixation. A distal cement restrictor (TECH FIG 7) is placed approximately 1 cm past the anticipated depth of stem insertion.

This helps avoid unnecessarily long cement mantles that are difficult to remove at revision, and it enhances cement pressurization.

The femoral canal is then irrigated using pulse lavage, dried using suction, and packed with vaginal packing or a surgical sponge.

Cement for the femoral side should be prepared under vacuum or using centrifugation, both of which increase cement strength by reducing cement porosity. Cement is then poured into a cement gun. The cement is ready to
be injected when it has reached an intermediate viscosity, low enough to be inserted with the cement gun and to easily interdigitate in cancellous bone, but high enough to allow pressurization.

- After ensuring that there is no air in the tip of the cement gun, cement is injected in a retrograde fashion from distal to proximal, allowing the cement to push the cement gun out of the canal.
- Once the canal is filled to the level of the neck cut, the tip is removed from the cement gun and replaced with a cement pressurizing device that occludes the proximal femoral canal.
  - Any holes in the femoral shaft must be occluded prior to cement pressurization.
  - As pressurization is performed, cement, fat, and marrow contents should be seen extruding from small vascular foramina in the femoral neck. When the pressurizer is removed from the femur, the void created should be filled with more cement.
- The surface of the cement is then dried with a sponge, and cement is used to coat the femoral stem, concentrating on the metaphyseal region. Both of these measures are intended to diminish the amount of blood, fluid, and other debris present in the cement and at the cement–prosthesis interface. Such impurities have been shown to have significant effects on cement strength.
  - If the femur has a relatively wide diaphysis, the addition of a distal centralizer to the stem is advised to reduce the risk of varus malpositioning.
  - The stem is best inserted when the cement is in the “medium dough phase.” The amount of time required for the cement to reach this state varies with room temperature and rate of mixing.
  - Pre-heating the stem will further reduce cement porosity and accelerate cement polymerization.\(^ {17}\)
  - To avoid the creation of voids in the cement mantle, the stem should be inserted in one continuous smooth motion, without adjusting varus/valgus or rotational alignment. Insertion is started by hand, impacting the insertion device with a mallet as needed.
  - Once the position of the trial stem has been reproduced, gentle pressure is maintained on the stem while excess cement is removed, and cement around the stem is pressurized by finger pressure.
  - When the cement has polymerized, the previously selected trial head is placed on the stem and the LTC, leg-length and soft tissue balance, and combined anteverision are reassessed.
  - Once the appropriate head is selected, the trunion of the stem is carefully cleaned and dried, and the implant is gently impacted in place.
  - The acetabulum is cleared of debris using irrigation and suction, and reduction is performed.

**TECH FIG 7 • A cement restrictor placed distal to the tip of the stem allows for cement pressurization. The appropriate depth of insertion is marked on the insertion device.**

**SOFT TISSUE REPAIR AND WOUND CLOSURE**

- Injection of the deep soft tissues (ie, hip capsule, gluteus medius tendon, vastus lateralis, and iliotibial band) with a combination of local anesthetic, narcotic, and either corticosteroid or nonsteroidal anti-inflammatory medication results in decreased postoperative pain and narcotic requirements.\(^ {18}\)
- After copious irrigation of all exposed tissues, an extended posterior soft tissue repair is performed (**TECH FIG 8**).
- The quadratus femoris is repaired to its insertion using nonabsorbable suture, along with repair of the gluteus maximus insertion if this tendon was released.
- A figure-8 suture is placed approximating the superior aspect of the piriformis to the abductor musculature; this suture is not tied initially.
- Repair of the short external rotators and posterior capsule to the posteromedial aspect of the greater trochanter is facilitated by two steps performed earlier in the case.
  - A nonabsorbable suture is passed through the superior lateral portion of the posterior capsular flap and the piriformis tendon in a single pass, with a second pass through the capsule and the conjoint tendon.
  - A second nonabsorbable suture is passed through the inferior lateral portion of the capsular flap and...
the obturator externus tendon, and then again through the capsule. These sutures typically are placed after acetabular cementing and before femoral preparation.

- During closure, the two sutures are passed through drill holes in the greater trochanter and tied to each other.
- To reduce operating time, the drill holes are created while waiting for the femoral cement to dry.
- Prior to tying the sutures, the leg is abducted and externally rotated, taking tension off the posterior soft tissue flap being repaired to the greater trochanter.
- The suture connecting the piriformis to the abductors is tied last.
- The repair should be inspected carefully to make sure that the posterior flap is in contact with the femur, rather than hanging by suture or sutures, before the fascia is closed.
- An inadequate repair can be revised easily if it is noticed at this time.
- The wound is once again copiously irrigated and routine closure of the fascia, subcutaneous tissue, and skin is performed.

### PEARLS AND PITFALLS

<table>
<thead>
<tr>
<th>Leg length and offset</th>
<th>Optimal function requires restoration of leg length and offset. Patients with particularly high offset should be warned that mild lengthening of the leg may be necessary to achieve appropriate soft tissue tension.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Indications</td>
<td>Concomitant spine pathology can lead to persistent symptoms after otherwise successful THA. Older, lighter, less active women with osteoporosis generally have excellent outcomes after cemented THA and may be spared the thigh pain that remains common after noncemented femoral fixation.</td>
</tr>
<tr>
<td>Exposure</td>
<td>Effort should be made to minimize soft tissue trauma. However, small skin incisions that limit exposure may place important deeper structures at risk for increased trauma.</td>
</tr>
<tr>
<td>Hypotensive anesthesia</td>
<td>Optimal cement fixation of the acetabular component is difficult to achieve without a dry surgical field, making hypotensive anesthesia a crucial aspect of cement technique.</td>
</tr>
</tbody>
</table>

### POSTOPERATIVE CARE

- Blood management
  - We currently recommend preoperative autologous blood donation to reduce postoperative exposure to allogenic blood.
  - Preoperative recombinant human erythropoietin may be considered in patients unable to donate blood.
  - Allogenic transfusion may be used as indicated for symptomatic anemia.
- Pain control
  - Patient satisfaction is improved by the use of multimodal analgesia protocols, combining soft tissue injections at the time of surgery, acetaminophen, nonsteroidal anti-inflammatory medications, and both long- and short-acting narcotics.
  - These regimens reduce both pain and narcotic requirements, thereby reducing perioperative nausea, emesis, sedation, and confusion, and enabling more rapid rehabilitation.
- Intravenous antibiotics
  - Antibiotics are given within 1 hour before surgery and continued postoperatively for 24 hours
  - Cefazolin is the preferred antibiotic.
  - Vancomycin or clindamycin typically are used in the patient allergic to penicillin or cephalosporins. Vancomycin may be preferable, as *Staphylococcus epidermidis* isolates often are resistant to clindamycin.
- Prophylaxis against venous thromboembolic disease
  - Sequential compression devices provide mechanical prophylaxis, which has been proven to reduce the risk of deep vein thrombosis (DVT), both as the sole mode of prophylaxis and as an adjunct to pharmacologic prophylaxis.
  - The optimal pharmacologic prophylaxis remains a matter of debate, but some form of prophylaxis should be continued after hospital discharge. We use a single dose of warfarin preoperatively on the day of surgery, a single dose of intravenous heparin given intraoperatively prior to hip dislocation, and adjusted-dose warfarin postoperatively for the first 2 to 3 days in all patients. Patients with a history of thromboembolic disease or who are otherwise deemed to be at high risk for thrombosis, as well as those with a prior indication for warfarin, are kept on extended warfarin prophylaxis after discharge.
  - A screening Doppler is performed prior to patient discharge. If it is negative, patients without any of the previously mentioned indications for warfarin are discharged on aspirin, 325 mg daily. If the Doppler is positive, patients are continued on warfarin at treatment doses.
  - Accelerated rehabilitation protocols further reduce the risk of thromboembolic disease, and are an important part of most multimodal prophylaxis regimens.
- Physical therapy
  - Posterior hip dislocation precautions are recommended for all patients undergoing total hip replacement through a posterior approach. A recent study challenging the need for precautions was performed at a center where the anterolateral approach is used. Surgeons employing the posterior approach should not assume that these findings can be generalized to all patients after THA.
outcomes

- Relief of hip pain and restoration of function are remarkable after THA. Thigh pain is rare after cemented THA, whereas it is relatively common after noncemented femoral fixation.
- The clinical success of cemented THA has been documented at long-term follow-up (FIG 3). Although function may decline with age and comorbidities, 94% of patients followed for 30 years were free from hip pain or reported minimal discomfort.26
- Minimum 25-year follow-up data after cemented THA using first-generation cement techniques is available from institutions in Minnesota1 and Iowa.5,6 Each center has reported a single-surgeon series consisting of consecutive cases performed in the late 1960s and early 1970s.
- Implant survivorship was 94% at 10 years, 90% at 15 years, 84% to 85% at 20 years, 77% to 81% at 25 years, and 68% at 30 years.
- Revision with removal of at least one component was required in 12% of hips at 30-year follow-up,6 with the remainder of the original implants either still functioning well in vivo (7%) or in place at the time of patient death (81%).
- Minimum 20-year follow-up data after cemented THA using improved cement technique in the 1970s and early 1980s is available from institutions in Iowa4,23 and Ontario.3,25
- Revision with removal of at least one component has been required in 3% to 10% of patients at 10 to 15 years and in 5% to 12% of patients at 20 to 25 years.
- Reasons for revision
  - Aseptic loosening accounts for most revision procedures after cemented THA, with reports ranging from 62% to 100%.1,3,16,23
  - Deep infection, recurrent dislocation, and periprosthetic fracture account for most other revisions.
  - Less common reasons for revision after cemented THA include osteolysis, isolated polyethylene wear, and technical errors such as leg-length discrepancy.
- Component fracture, which was a major cause of revision with early implant systems, is very uncommon with modern implants.

complications

- Embolism of fat and bone marrow occurs whenever the marrow space of a long bone is instrumented, but it results in fat embolism syndrome. Cement fixation of the femoral component may increase the quantity of fat displaced, the consequent pulmonary shunt, and the risk of fat embolism syndrome.23 For this reason, we prefer to avoid cement fixation in patients with significant cardiopulmonary disease.
- Venous thromboembolism is common in THA if prophylaxis is not used. Most prophylactic regimens are associated with low rates of symptomatic DVT and pulmonary embolism, with fatal pulmonary embolism occurring in fewer than 0.5% of patients. Aggressive pharmacologic anticoagulation has been proven to reduce the rate of asymptomatic DVT, but no regimen has been found to decrease the low rate of fatal pulmonary embolism.
- Cardiopulmonary complications are uncommon with appropriate preoperative medical optimization and conservative surgical indications, but at-risk patients should be monitored carefully in the perioperative period.
- Clinically meaningful leg-length inequality is an avoidable complication in most patients. In a prospective study,22 the methods for equalizing leg lengths described in this chapter resulted in postoperative leg-length inequality that averaged +2.6 mm (range, −7 mm to +9 mm), with 87% having inequality of 6 mm or less. None of the patients reported symptoms of leg-length inequality or required the use of a shoe lift.
- Infection can be a devastating complication after total hip replacement. The use of perioperative antibiotics and of antibiotic-laden bone cement3 have both been associated with decreased risk of deep infection.
  - Other interventions such as the use of laminar flow and body exhaust suits have been demonstrated to decrease the risk of infection in the setting of inconsistent antibiotic use, but no additive benefit in the setting of consistent use of prophylactic antibiotics has been proved.
  - The use of iodine-impregnated adhesive plastic drapes and the minimization of operating room traffic may also reduce bacteria counts in the surgical wound.
  - Dislocation after total hip replacement can cause significant aggravation to the patient and the physician, and is one of the more common causes of revision surgery. The risk of dislocation is minimized when the reconstruction restores leg length, offset, and center of rotation, with appropriate femoral and acetabular anteversion.
  - Anterior, anterolateral, and direct lateral approaches have been associated with the lowest risk of dislocation. We prefer the posterior approach for the reasons already stated. Although posterior approaches may increase the risk of dislocation slightly, this risk can be mitigated by a careful posterior soft tissue repair.
  - Periprosthetic fracture can occur intra- or postoperatively. The key to management of intraoperative fractures is intraoperative recognition, as most can be managed expeditiously at the time of surgery. If an appropriate starting point is used for femoral preparation, intraoperative fractures in primary

Figure 3: Radiograph of cemented total hip arthroplasty.
cemented THA are uncommon. Postoperative fractures typically are associated with trauma, often in the setting of osteolysis, and their management is beyond the scope of this chapter.

- Aseptic loosening is the most common cause of failure after cemented THA. The risk of aseptic loosening can be decreased by use of well-designed implants and modern cement technique. Nevertheless, several patient factors influence rates of aseptic loosening after cemented THA.
  - Male gender is strongly associated with increased risk of revision for aseptic loosening. The risk of aseptic loosening is inversely correlated with risk of revision for aseptic loosening. Twenty-five-year survivorship free of revision for aseptic loosening was 68.7% in patients who were younger than 40 years of age at the time of primary arthroplasty, and 100% in patients older than 80 years of age, with incremental increases in survival observed for each decade of increased age between 40 and 80.
  - Osteolysis, a common cause of failure in uncemented implants, is reported less commonly after cemented THA, possibly related to decreased polyethylene wear in cemented THA. Although “ballooning” osteolysis is uncommon when cement is used, fixation failure in cemented THA seems to be related to the biologic reaction to wear debris.
  - Sciatic nerve palsy is an uncommon complication after cemented THA. It most commonly occurs when the operated extremity is lengthened substantially after a longstanding (especially congenital) shortening of the limb, resulting in traction-related nerve ischemia. We routinely palpate the sciatic nerve before the hip is dislocated and again after the arthroplasty is performed, to assess whether the tension in the nerve has been excessively increased.
  - The sciatic nerve may also be compressed under the tendon of the gluteus maximus during surgery if the hip is maintained in severe flexion and internal rotation. For this reason, Hurd et al recommended routine release of the gluteus maximus tendon during THA.

REFERENCES

DEFINITION
- Total hip arthroplasty is the standard of care for symptomatic degenerative joint disease of the hip that is unresponsive to nonoperative treatment.
- Cementless total hip arthroplasty has demonstrated excellent mid- to long-term results.
- The acetabular component obtains initial fixation through a press-fit and has a surface that allows for in- or on-growth of bone.
- The femoral component obtains initial fixation through a press-fit in either the metaphysis or diaphysis and has a surface that allows for in- or on-growth of bone. The metaphyseal-fit prosthesis may be either wedge-shaped or fit-and-fill.

ANATOMY
- The acetabulum must be exposed so that the anterior and posterior walls, superior dome and rim, and teardrop are visualized.
- The proximal femur must be exposed so that the periphery of the proximal femoral neck cut is visualized.

PATHOGENESIS
- Degenerative joint disease of the hip is the endpoint of many hip disorders, including osteoarthritis, inflammatory arthritis, dysplasia, osteonecrosis, trauma, and sepsis.

NATURAL HISTORY
- Degenerative joint disease of the hip often follows a variable symptomatic course. It is unknown why some patients progress more rapidly than others and why some patients are more symptomatic than others.

PATIENT HISTORY AND PHYSICAL FINDINGS
- The history should be directed to determine whether the patient's pain is extrinsic or intrinsic.
- The patient's pain may be extrinsic (eg, lumbar radiculopathy, intrapelvic pathology), and hip arthroplasty may fail to relieve the patient's pain completely, even in the face of severe degenerative changes of the hip.
- Pain usually is located in the groin but may be located in the medial thigh, buttock, or the medial knee.
- Range of motion (ROM) should be observed. Normal ROM of the hip is an arc of motion of 120 to 140 degrees of flexion–extension, 60 to 80 degrees of abdution–adduction, and external–internal rotation of 60 to 90 degrees. Loss of motion may be due to pain, contracture, or abnormal biomechanics.
- Nonoperative treatment must be optimized before consideration is given to surgery.
- Leg lengths should be measured and recorded preoperatively, and the patient should be counseled as to reasonable postoperative expectations.

Examinations to perform include:
- Trendelenburg test. The test is positive if the contralateral hip drops inferiorly; this may indicate that the hip abductors are compromised.
- Hip flexion–internal rotation. The test is positive if the patient's pain is recreated. Pain that is not recreated with this examination may be from an extrinsic source.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- Plain radiographs, including anteroposterior (AP) views of the pelvis and AP and true lateral views of the hip, should be obtained to evaluate the anatomy, assess for deformity, and devise an adequate plan preoperatively (FIG 1).

DIFFERENTIAL DIAGNOSIS
- Lumbar radiculopathy
- Spinal stenosis
- Sacroiliac degenerative joint disease
- Intra-abdominal pathology
- Intrapelvic pathology
- Neuropathy
- Meralgia paresthetica
- Complex regional pain syndrome
- Vascular claudication
- Primary bone tumors
- Metastasis
- Infection

FIG 1 • AP radiograph of the hip demonstrates advanced degenerative changes of osteophytes and joint space obliteration.
NONOPERATIVE MANAGEMENT
- Acetaminophen
- Nonsteroidal anti-inflammatory drugs
- Glucosamine
- Chondroitin sulfate
- Physical therapy

SURGICAL MANAGEMENT
- The primary indication for cementless total hip arthroplasty is painful, severe degenerative joint disease of the hip that has been nonresponsive to appropriate nonoperative treatment modalities.

Preoperative Planning
- Preoperative planning for routine cementless primary total hip arthroplasty can be accomplished with plain radiographs at standard magnifications.
  - Standard templates are available for the components, and many are available for digital templating as well.
  - The acetabular component is placed so that the inferomedial edge of the cup is at the radiographic “teardrop.” The inclination is 35 to 45 degrees, and the cup should contact the superolateral rim of the acetabulum.
  - The femoral component is placed so that the center of rotation is at the level of the greater trochanter. The femoral offset should be reproduced. However, the femur must be internally rotated 10 to 15 degrees on the radiograph to bring the femoral neck into the plane of the radiograph. Externally rotated femora will appear to be in coxa valga.
  - Proximal-fit femoral prostheses are designed to obtain fit in the metadiaphyseal region.
  - Diaphyseal-fit femoral prostheses are designed to obtain fit in the diaphysis.

Positioning
- The patient is positioned according to surgeon preference and in accordance with the surgical approach.
  - The hip should be draped in such a fashion as to allow a wide surgical exposure should an extensile approach be required in the event of a complication.
  - The pelvis must be stabilized in a secure fashion to avoid pelvic tilt, which may affect the surgeon’s perception of the acetabular position.

Approach
- The hip can be exposed for primary routine arthroplasty via a variety of approaches:
  - Anterior
  - Anterolateral
  - Direct lateral
  - Posterior
  - Two-incision
  - Small-incision variants of these approaches

ACETABULAR EXPOSURE
- The approach to the hip is chosen according to the surgeon’s preference. The approach illustrated here is the direct lateral (modified Hardinge) approach in the supine position.
  - Retractors are placed in the anterior, superior, and inferior positions, thereby exposing the entire periphery of the acetabulum (TECH FIG 1).
  - The labrum is resected.
  - The soft tissue in the cotyloid fossa is removed, allowing exposure of the medial wall and teardrop.

TECH FIG 1 • Acetabular exposure.
A. Supine position for modified Hardinge approach. B. Completed acetabular exposure. The medial wall and native acetabular anatomy are easily visualized. C. Labrum is resected. D. Osteotome removes osteophytes from cotyloid fossa. E. Currette removes remaining tissue to expose teardrop.
ACETABULAR PREPARATION

- Before reaming, the entire periphery of the acetabulum, medial wall, and teardrop must be directly visualized (TECH FIG 2).
- The initial reaming must be done with moderate pressure until the quality of bone is assessed. The goal of the initial reaming is to medialize the reamer fully. The cotyloid fossa should be eliminated without penetrating the medial wall.
- Reaming then proceeds sequentially. The goal is to recreate the center of rotation by placing the inferomedial aspect of the socket at the level of the teardrop with the component inclined at 35 to 45 degrees and with 10 to 20 degrees of anteversion and with good initial fixation obtained through a press-fit.
- The templated size should be used as a guide; intraoperatively, an increase or decrease in cup diameter may be found to be appropriate.
- Failure to recognize the need for a different cup diameter may lead to iatrogenic fracture or a failure to achieve initial fixation.
- The bony bed should be bleeding but not devoid of sclerotic bone.
- The pelvis must remain in a stable position to avoid malpositioning of the acetabular component.

![TECH FIG 2](image1)

TECH FIG 2 • Acetabular preparation. A. Initial reaming to medialize acetabulum fully. B. Reaming completed to medial wall. C. Reaming proceeds sequentially at 35 to 45 degrees of abduction and 10 to 20 degrees of anteversion.

ACETABULAR COMPONENT IMPLANTATION

- The position of the pelvis is reassessed. Any tilt is corrected.
- The trial component or reamer is used to assess bone coverage of the component and position (TECH FIG 3). If the trial or reamer is not seated properly, then further reaming may be necessary. If deemed appropriate, implantation of the actual component may proceed.
- The actual implant should be 1 to 2 mm larger than the last reamer. The surgeon must know the actual

![TECH FIG 3](image2)

TECH FIG 3 • Acetabular component implantation. A. Final reamer is used to assess component position, bone coverage, and seating. B. Acetabular component is implanted. C. Central hole is used to verify that the cup is fully seated. D. Actual liner is inserted into the cup.
diameter of the implant, taking into account any rim or coating.
- Implants that are larger than the size of the last reamer by 4 mm or more are associated with risk of fracture.
- The acetabular component is then implanted, with care taken to medialize the implant. The inferomedial aspect of the cup should be at the level of the teardrop in 35 to 45 degrees of abduction and 10 to 20 degrees of anteversion.
- A trial liner or the actual liner is then inserted.

**FEMORAL EXPOSURE**

- The femur is exposed by elevating it out of the wound with a retractor (Bennett or double-footed).
- The periphery of the femur is exposed with another retractor (**TECH FIG 4**).
- The soft tissues must be protected so that iatrogenic damage by reamers or broaches is avoided.

**TECH FIG 4** • Femoral exposure. The femur is elevated and exposed with two double-footed retractors to allow atraumatic broaching.

**FEMORAL PREPARATION (PROXIMAL-FIT PROSTHESIS)**

- The femur is prepared as delineated by the surgical protocol for each prosthesis (**TECH FIG 5**). The surgeon should be familiar with the prosthesis and all of the available options and idiosyncrasies.
- The proximal-fit prosthesis usually requires a starter reamer, which is used as a canal-finder. In addition, the reamer should be laterialized to avoid broaching and subsequent varus positioning of the implant.
- The femur then is broached sequentially, with care taken to lateralize the broach. Broaching is complete when the broach ceases to advance, the pitch of impaction increases, and good cortical contact is obtained.

**TECH FIG 5** • Femoral preparation.  
A. Rongeur is used to clear tissues and lateral cortical bone.  
B. Curette used to find canal.  
C,D. Canal is reamed to open canal, and care is taken to lateralize.  
E. Broaching proceeds. (continued)
The implant chosen usually matches the size of the last broach.

- The proximal-fit femoral component is inserted, with care taken to avoid varus positioning (TECH FIG 6).

- The implant is impacted until it ceases to advance, the pitch of impaction increases, there is good cortical contact, and the implant has reached the level of the last broach.

- The templated size should be used as a guide, and an increase or decrease in stem size intraoperatively may be appropriate.

- Failure to recognize the need for a different size may lead to iatrogenic fracture or failure to achieve initial fixation.

- A standard or varus neck is selected based on the soft tissue tension and the patient’s anatomy.

**FEMORAL COMPONENT IMPLANTATION (PROXIMAL-FIT PROSTHESIS)**

- Improper broaching can lead to fracture, malposition, or undersizing.
- The component should be anteverted 10 to 15 degrees.
- The greater trochanter can be used as a reference to recreate the center of rotation.
- It may be necessary to adjust the neck cut to allow for further seating of the prosthesis.

**SOFT TISSUE TENSION/LEG-LENGTH DETERMINATION**

- The hip is trial reduced and assessed for soft tissue tension, stability, ROM, impingement, and leg length.
- The soft tissue tension should allow for no more than 1 to 2 mm of toggle (TECH FIG 7).
- The hip should be stable within the patient’s physiologic ROM. If instability exists, the position of the components must be reassessed.
- The ROM should be physiologic for the patient.
Postoperative Care

- Weight bearing after cementless total hip arthroplasty is controversial. Some surgeons routinely restrict weight bearing for 6 weeks, whereas others allow weight bearing as tolerated.
- Hip precautions are prescribed according to the approach.
  - Posterior approaches avoid flexion, internal rotation, and adduction, whereas anterior approaches avoid extension, external rotation, and adduction.
  - The hip precautions are discontinued at 6 weeks.
  - Some surgeons who perform the anterior approach have discontinued the use of traditional hip precautions.20

Outcomes

- The survivorship of cementless total hip arthroplasty components generally has been excellent, although isolated reports of high failure rates exist for certain designs, which have subsequently been abandoned. Most modern, uncemented acetabular and femoral components have reported survivorship of 95% to 100% at mid- to long-term follow-up.1–19, 21–23
Overall survival of cementless acetabular components has ranged from 83% to 99.1% at 8.5 to 16.3 years of follow-up.\textsuperscript{1,3,6,7,10–12,15,21,23} The reported survivorship of cementless femoral components has ranged from 82% to 100% at 6.6 to 17.5 years of follow-up.\textsuperscript{1,2,4,5,8,9,12–14,16–18,22} The main limitation to long-term clinical success has been wear and subsequent osteolysis.

**COMPLICATIONS**

- Iatrogenic fracture
- Stress shielding of proximal bone
- Blood loss
- Infection
- Neurovascular injury
- Anesthetic and medical complications
- Loosening
- Osteolysis

**REFERENCES**

Surface replacement is a significant development in the evolution of hip arthroplasty. Hip resurfacing is based on the premise that femoral bone can be preserved. The femoral head is “resurfaced” by insertion of a cemented component. The cup is press-fit.12

**Resurfacing Systems**

Several hip resurfacing devices of various designs are available, but the most critical factor in resurfacing is the surgeon’s level of expertise. These various devices differ in terms of material, surface treatments, cup design, manufacturing process, carbide content, component thickness, clearance, possibility of including a cement mantle under the femoral component, fixation methods, and size ranges offered (Table 1).

**SURGICAL MANAGEMENT**

**Indications**

- Hip resurfacing is used optimally in younger, active patients with good bone quality.
- This procedure is indicated for a degenerative hip joint with pain and decreased range of motion.
- When joint-preserving procedures such as femoral osteotomy, acetabular osteotomy, or vascularized bone grafting are not ideal for an early stage of unambiguous coxarthrosis, hip resurfacing can be considered.
- Resurfacing usually is reserved for patients with good bone stock, high activity level, and a need for a high degree of motion.
- Hemiresurfacing, in which only the femoral head is resurfaced, has largely been abandoned because it provided suboptimal results.
- Resurfacing recently was approved by the U.S. Food and Drug Administration.
- General indications for hip resurfacing are as follows:
  - Primary osteoarthritis
  - Secondary osteoarthritis as sequel of childhood disease, including hip dysplasia or infection
  - Osteonecrosis of the femoral head
  - Post-traumatic arthritis
  - Ankylosing spondylitis
  - Rheumatoid arthritis

**Contraindications**

- Abnormal anatomy of femoral head or neck
- Severe limb-length discrepancy that may require some correction during arthroplasty
- Severe bone deficiency
- Large and cystic lesions of the femoral head
- Severe dysplasia, because screw fixation for the acetabulum cannot be performed with resurfacing

**Special Considerations**

**Osteonecrosis of the Femoral Head**

- Osteonecrosis of the femoral head presents a special problem for hip resurfacing.
- The presence of a necrotic lesion of the femoral head can compromise fixation of the component.
- In general, survival of hip resurfacing is lower for avascular necrosis than for osteoarthritis in the counterpart hip.3

**Use of a Computer-Assisted Navigation System**

A computer-assisted navigation system is an intraoperative image-guided localization system used to enable proper cutting of bone and exact location of the implants in total knee or total hip arthroplasty (THA) and in minimally invasive surgery.

Although hip resurfacing arthroplasty has been used for a long time with acceptable results without any navigation system, one of the main concerns following resurfacing arthroplasty is femoral neck fracture.

- In general, slight valgus positioning of the implant is recommended to reduce the tension and shear stresses across the head–neck junction, but intraoperative neck notching during femoral cutting often is a consequence of extreme valgus position.
- Many mechanical femoral alignment guides have been developed to help surgeons achieve optimal positioning of the femoral implant.
- As for THA, early loosening or dislocation resulting from impingement due to the malposition of both components should be prevented.12
- In hip resurfacing arthroplasty, avoidance of femoral notching by the femoral component and the position of the stem of the femoral component are critical. This may be technically difficult, even for an experienced surgeon, and it adds time to the procedure.
- Computer-assisted navigation systems have been developed to surmount the intrinsic limitations of manual techniques.

Intraoperative navigation can demonstrate real-time positioning of instrumentation by imaging, thereby improving the accuracy of component positioning in hip resurfacing arthroplasty.

- Specific surface landmarks may be difficult to make out, however, and registration procedures often are the most time-consuming and accuracy-related segment of the procedure.
- Irregular soft tissue distribution around the femoral neck also can affect navigation precision.

Surgical navigation may be especially helpful during femoral procedures.

- To reduce the potential risk of femoral neck fracture, we perform total hip resurfacing arthroplasty using computer-assisted navigation.
- We have used the hip resurfacing systems with Vectorvision (BrainLAB, Munich, Germany) since 2005 (FIG 1).10

When using an image-free hip navigation system, the surgeon must digitize the pelvic and femoral planes of the patient to determine the individual pelvic and femoral coordinate system for prosthesis positioning.

**Preoperative Planning**
- Templates are used to determine approximate component sizes. Standard-sized conventional radiographs must be used rather than digital films, and the magnification factor must be taken into account.
- The femoral component must be sized such that there is no over-reaming of the femur or risk of notching of the neck. Oversizing also should be avoided to preserve acetabular bone stock.
- Femoral component alignment is the most important preoperative consideration. Varus positioning must be avoided—neutral or slight valgus alignment is preferred (FIG 2).
- When optimum femoral template positioning has been achieved, the distance from the tip of the greater trochanter to the pin insertion point on the lateral femoral cortex is measured with the ruler printed on the template.
- The relation between the exit-point of the guidewire on the template relative to the lesser trochanter should be noted and reproduced during surgery.
- An acetabular component should be selected of the size that fills the acetabular fossa and accommodates the selected femoral component.

**Approach**
- All of the standard exposures of the hip have been successfully used to perform surface replacement.
- Hip resurfacing is technically demanding, and the surgical approach used should allow adequate exposure of the acetabulum and proximal femur without compromising postoperative muscle function.
- The posterior approach is the most popular approach for total hip resurfacing.
- The anterior approach, the exposure advocated by Wagner, is not popular.
- The anterolateral approach was described by Hardinge and modified by Learmonth.
- Exposure of the femoral head is achieved by flexion, abduction, and external rotation of the lower extremity.

Exposure of the acetabulum is accomplished by depressing the femoral head into a posterior and inferior position.
- This approach has the advantage of preserving the posterior retinacular vessels, which reduces the possibility that an iatrogenic avascular state will develop postoperatively in the remaining femoral head.
- Critics of this approach believe that the exposure offered is inadequate, leading to a greater risk of complications and improper component positioning of both implants in total hip resurfacing. There may be a higher incidence of heterotopic new bone formation, and decreasing abductor muscle function often is compromised following this approach.
- The trans-trochanteric approach for hip resurfacing was popularized by Amstutz.
- This approach provides excellent exposure, but it rarely is used for this operation, primarily because of problems associated with trochanteric osteotomy and a higher incidence of heterotopic ossification.
- The posterior or posterolateral approach is the standard approach used for total hip resurfacing.
In this approach, the tendon of insertion of the gluteus maximus is released to allow easy anterior displacement of the femur. The capsule and synovium around the femoral neck are preserved as much as possible to prevent further vascular damage to the femoral neck and head. The femoral head then is dislocated (FIG 3).

The femoral neck is sized using neck gauges. Sizing also gives an idea about the minimum acetabular size required. Usually, the acetabular preparation is done first, unless the femoral head is especially large, which results in inadequate acetabular preparation. In such cases the femoral head is prepared to one or two sizes larger than the targeted femoral component size.

POSTEROLATERAL APPROACH

Exposure

- The patient is placed in the lateral position.
- The hip is flexed to 45 degrees, and a straight incision is made centered on the posterior edge of the greater trochanter.
- Alternatively, the hip is extended and a conventional incision, curved posteriorly, is made (TECH FIG 1A).
- The fascia lata is incised, the fibers of the gluteus maximus are split, and a Charnley retractor is inserted (TECH FIG 1B).
- The tendon of insertion of the gluteus maximus usually is released to allow subsequent easy anterior displacement of the femur; the underlying perforator vessels may require coagulation (TECH FIG 1C).
- The trochanteric bursa is divided and swept posteriorly, after which the sciatic nerve may be easily seen or palpated.
- The posterior edge of the gluteus medius is retracted anteriorly to reveal the piriformis tendon.
- The fibers of the gluteus minimus are separated from the superior border of the piriformis tendon.
- The interval between the gluteus minimus and the superior acetabulum and superior hip capsule is developed with electrocautery.
- The hip is held in internal rotation, and the piriformis tendon is divided as close as possible to its insertion, along with the hip capsule.
- The other external rotators and the hip capsule are divided with electrocautery, leaving a cuff of quadratus femoris for later suturing.
- The joint capsule is incised along the line formed by the superior margin of the piriformis muscle. The posterior capsule is detached cautiously, along with the base of the femur neck, to save intracapsular blood vessels around the femoral neck.
- The femoral head is dislocated, the hip is fully extended (by bringing the knee to the midline), and maximum internal rotation of the leg is performed (TECH FIG 1D).

TECH FIG 1 • A. Posterolateral approach. The patient is in the lateral position with the affected hip flexed 45 degrees. A straight incision is made at the posterior border of the greater trochanter. B. The gluteus maximus fibers are split proximally and the iliotibial band is incised distally. C. A diathermy is used to release the insertion of the gluteus maximus tendon, leaving behind a small fringe for later suturing. Perforator vessels in this area may cause furious bleeding, requiring ligation or cauterization. D. Circumferential capsulotomy. With the hip fully extended and in maximal internal rotation, the anteroinferior capsule is divided inferiorly. The hip is then flexed to 45 degrees in maximum internal rotation and the anterosuperior hip capsule is divided superiorly. The capsulotomy is extended down to meet the previous inferior cut, giving a full circumferential capsulotomy. E,F. Diagram illustrating sizing of the femoral neck. The neck is sized in its maximum diameter.
- The anteroinferior hip capsule is divided, beginning inferiorly, just in front of the psosas tendon, using Muller capsular scissors or electrocautery.
- The femoral neck is sized using neck gauges or templates (TECH FIG 1E,F); this also gives an idea about the minimum acetabular size required.
- An anterolateral soft tissue pocket is created using a curved periosteal elevator or a Cobb elevator.
- A Hohmann retractor is placed over the anterosuperior acetabulum and impacted into the anteroinferior iliac spine, and the leg is externally rotated to allow the femoral head to prolapse under the abductors into the pocket.

**Acetabular Preparation**
- A pin retractor (Judd pin) is inserted into the ischium, retracting the posterior capsule and external rotators.
- Two Hohmann retractors are placed from inferior to the teardrop, directed antero- and posteroinferiorly (TECH FIG 2A).
- The labrum, transverse acetabular ligament, and other soft tissue in the cotyloid fossa are excised, giving a complete view of the bony acetabulum.
  - Sequential reaming is performed (TECH FIG 2B), with under-reaming by 1 to 2 mm.
- An acetabular component that provides the best possible fit without reaming excess acetabular bone is preferred; this choice then determines the size of the femoral component.
  - A trial cup is inserted and tested for stability (TECH FIG 2C).
- The true acetabular component is then inserted in “native” version, usually 20 degrees, and at a 45-degree angle (TECH FIG 2D).
- Any protruding acetabular osteophytes should be removed.
- The Hohmann retractors and pin retractor are removed.

**Inserting the Guide Pin**
- The limb is then hyperrotated to expose the femoral head.
- Lines are drawn on the center of the femoral head and neck in both anteroposterior (135–140 degrees of neck-shaft angle) and lateral planes (normal anteverision) and are extended up into the femoral head, where they intersect (TECH FIG 3A,B).
  - The intersection point should be the entry point for the guide pin.
- A guide pin is drilled into the femoral head and neck using a guide instrument (TECH FIG 3C).
  - A stylus is placed over the guide pin. This should pass around the femoral neck without impingement (TECH FIG 3D) to avoid notching of the femoral neck.
- The guide pin normally is inserted from the superior part of the femoral head about 1 to 2 cm above the fovea.
  - In the coronal plane, 5 to 10 degrees of valgus is desirable; a 135- to 140-degree angle must be maintained with the long axis of the femoral neck (TECH FIG 3E).
  - Because a deformed femoral head or osteophytes around the femoral head and neck may make it difficult to recognize the actual state and relation of the femoral head and neck junction, excessive osteophytes should be removed carefully before femoral pinning.

**Femoral Head Resurfacing**
- In most systems, femoral head preparation is done using cannulated reamers that pass over the previously inserted femoral guide pin (TECH FIG 4A).
- Consecutive reaming or milling using specialized instrumentation forms the femoral head into a chamfer-cut cylindrical shape (TECH FIG 4B–D).
- Non-impinging osteophytes present on the femoral neck are best left untouched.
  - Any necrotic bone should be removed.
- The femoral head is then pulse lavaged, and a suction vent is placed into the lesser trochanter to keep the femoral head dry and to prevent embolism (TECH FIG 4E).
- A number of cement keyholes are drilled into the femoral head (TECH FIG 4F).
- A final check is made to confirm that there has been no notching from the trial component (TECH FIG 4G).
TECH FIG 3 • A, B. Planning the guidewire entry point in the AP plane. A line is drawn in the mid-lateral plane of the femoral neck. A second line is drawn in the center of the femoral neck such that it is parallel to the calcar femorale. This gives the guide pin a valgus orientation of about 5 to 10 degrees. The point where the two lines intersect, usually 1 to 1.5 cm superior to the fovea, should be the entry point for the guidewire. C. Planning the guidewire entry point in the superoinferior plane using guide instruments from various companies. D. Planning for slightly valgus placement for the femoral guide pin and checking for notching in the femoral neck. The stylus on the guide pin should move freely around the femoral neck at the head–neck junction without impingement. Moreover, the surgeon can confirm the head size through this procedure. E. The angle in the coronal plane is checked intraoperatively using a goniometer.

TECH FIG 4 • A. The guide rod is inserted after drilling over the guide pin, and the head cutter is advanced through the guide rod. During this procedure the surgeon should check for and avoid femoral notching at the head–neck junction. A head cutter one size larger may be used initially. B. After safe cutting has been accomplished, all instruments are removed, and the top of the head guide is placed through the prepared femoral head. The inferior margin of the guide is placed next to the superior margin of the head–neck junction. The locking lever is securely fixed, and the top area is resected using a saw. C. The chamfer cutter for the femoral head then is used on the reinserted guide rod. D. The final shape of the chamfer-cut femoral head. E. The prepared femoral head is irrigated using a motorized pulsatile lavage instrument. F. Multiple cement keyholes are made, being sure to keep the femoral head dry. G. A head trial is used to recheck the possibility of femoral notching and to determine the point between inferior margin of the trial and femoral head–neck junction.
Cementing

- Bone cement is placed into the femoral component, which is then impacted onto the resurfaced femoral head (TECH FIG 5A,B).
- Alternatively, in case of femoral head defect after curettage of necrotic bone, cement is applied to give a uniform 2-mm cement mantle around the femoral head (TECH FIG 5C), and the femoral component is placed over the head and lightly tapped into place (TECH FIG 5D).

- Excess cement is removed and pulse lavage is used.
- The joint is then reduced and tested for stability and range of motion.

Wound Closure

- Good closure of the capsule and the external rotators is important.
- The tendinous insertion of the gluteus maximus also is repaired, and the fascia lata, subcutaneous fat, and skin are closed.

SPECIAL TECHNIQUE FOR OSTEONECROSIS OF THE FEMORAL HEAD

- Because the surgical approach and acetabular preparation are almost the same, only the technique for the femoral side is described.

Femoral Preparation

- Accurate placement of the guide pin can be accomplished using pin alignment guides or a navigation system (TECH FIG 6A,B).
- In most systems, femoral head reaming is performed by cannulated reamers that pass over the central guide pin.

- A series of reaming or milling devices form the femoral neck into a cylindrical shape (TECH FIG 6C).
- To reduce the stress resulting from femoral notching, reaming should be stopped before the peripheral rim of the distal part of femoral head is cut.
- The remaining distal rim of the femoral head is carefully removed using a rongeur (TECH FIG 6D).
- After chamfer cutting, the remaining necrotic area of the femoral head can be seen clearly (TECH FIG 6E).
- Using a small curette and rongeur, the remaining necrotic area is removed and irrigated with aseptic...
saline to remove tiny fragments of bone debris (TECH FIG 6F).

- The trial femoral head is inserted, and the percentage of volume loss after removal of necrotic bone in the trial is measured (TECH FIG 6G).

- In our experience, if the volume loss is less than 50% and the necrosis does not extend to the lower margin of the trial in any circumference of the femoral head and neck junction, resurfacing can be accomplished.

- Otherwise, we recommend either metal-on-metal THA with a modular large-diameter femoral head or the surgeon’s preferred conventional THA if the acetabular side is not yet finished for hip resurfacing.

**Cementing**

- Using pulsatile lavage, thorough saline irrigation is repeated, taking care to keep the femoral head dry. A special suction system is used during the preparation of bone cement (TECH FIG 7A).

- The bone defect is filled with bone cement and pressurized.
The femoral component is placed on the femoral head and impacted gently, with the cement inside the femoral component removed as a volume half using a cement syringe (TECH FIG 7B–D).

The femoral component is applied to the femoral head with an impactor, and extruding cement is removed with a curette, continuing until the bone cement hardens (TECH FIG 7E–H).

The femoral component is applied to the femoral head with an impactor, and extruding cement should be removed with a curette, continuing until the bone cement becomes solid.

**HIP RESURFACING USING A NAVIGATION SYSTEM**

**Patient Positioning**

At our institution, we use a posterolateral approach for hip resurfacing arthroplasty. When we use the hip resurfacing systems with image-free navigation for an acetabular procedure, certain initial maneuvers must be done with the patient in the supine position before moving the patient to the lateral position and undertaking the posterolateral approach, because pelvis registration cannot be performed conveniently in the lateral position.

Once the pelvis registration has been completed, the patient can be moved to the lateral position.

If the surgeon uses the navigation system only on the femoral side, the supine position for acetabular registration is not needed, and femoral registration is performed during surgery with the patient in the lateral position.
Precise location of the registration points is a key factor in ensuring proper matching at every step.

**Pelvis Registration**

- A small-step incision is made on the iliac crest of the operative side, and the fixation pin is inserted for the reference array using an automatic drill at low speed (TECH FIG 8A,B).
  - The second pin is inserted in the same manner using a drill template (TECH FIG 8C).
- Once two pins have been inserted, the bone fixator and the pelvis reference array are attached (TECH FIG 8D).
- The bone fixator should remain attached until the end of the entire navigation procedure.

- The plane of the pelvis is defined by entering points on the pelvis according to the navigation software (TECH FIG 8E,F).
  - Bony landmarks of interest are the left and right anterior superior iliac spine and the most anterior parts of both pubic bones, which, in most patients, are the pelvic tubercles (TECH FIG 8G,H).
- Once registration has been completed, the pelvis reference array is removed without dislodging the fixation pins and bone fixator (TECH FIG 8I).
- The reference array is stored in a sterile location until it is reattached.

**TECH FIG 8**

- A. The anterior pelvic plane is defined using four points: the operated and contralateral sides of the anterior superior iliac spine and the most prominent pubic points on both the operated and the contralateral sides. 
- B. After local sterilization, a small stab incision is made on the operated iliac crest, and the fixation pin is inserted with a low-speed automated drill. The fixation pins should not be inserted near the anterosuperior iliac spine point, because this point is required for pelvic registration. 
- C. The second pin is inserted in the same manner using a drill template. 
- D. Once the second fixation pin has been inserted correctly, the bone fixator is attached and the pelvic reference array is corrected to it. The reference array should be detected by the cameras both in supine and ateral positions during the operation. 
- E. The pelvic plane is defined by entering points on the pelvis as prompted by the software. 
- F. The pointer is put in the left anterosuperior iliac spine. 
- G, H. The pointer is placed on the right pubic point according to the navigation system. 
- I. Once registration has been completed, the pelvis reference array is removed without dislodging the fixation pins and bone fixator.
TECH FIG 9 • A. When the pelvis registration procedure is finished, the patient is moved into the lateral decubitus position. During this change in the patient’s position and draping, the surgical team should pay attention to the acetabular fixator and pins to protect them from contamination or loosening. B. With the patient repositioned and secured, the surgical area is sterilized and the patient is draped.

Repositioning the Patient

- When the pelvis registration procedure is finished, the patient is moved into the lateral decubitus position, and the surgical area is sterilized and draped thoroughly (TECH FIG 9).

- During draping, the surgical team should pay attention to the acetabular fixator and pins to protect against contamination or loosening.

Acquiring Acetabular Landmarks

- The skin is incised in a routine manner, and the acetabulum is exposed.

TECH FIG 10 • A,B. Multiple point acquisition on the cotyloid fossa, the deeper part of the acetabulum, is used to register bony areas. Points acquired in this way are used to calculate the three-dimensional model. The number of points to be acquired is shown in the center of an acquisition clock. C,D. Acquiring points on the acetabular wall. E,F. Once the bone model has been calculated, pelvis registration is verified.
■ Multiple landmark acquisition is used to register the cotyloid fossa and acetabular surface, including margins (TECH FIG 10A–D).
■ To begin multiple landmark acquisition, the tip of the pointer is touched to the required structure and pivoted slightly.
■ Points are acquired by sliding the pointer tip along the defined structure.
■ Once the bone model has been calculated in the navigation monitor, pelvis registration should be verified immediately (TECH FIG 10E,F).

Inserting the Acetabular Cup
■ To insert the cup at the desired angle, the bone must be reamed at the same angle as the planned cup (TECH FIG 11A).
■ The acetabulum initially is reamed with an 8-mm diameter reamer, which is smaller than the planned cup size (TECH FIG 11B,C).
■ Subsequent reaming can then continue in increments of 2 mm.
■ The planned inclination and version values for the implant are shown during reaming, and the values are updated dynamically (TECH FIG 11D).
■ Once the reamer has been navigated to the planned position and reaming has been completed, a trial cup generally is used to confirm that the selected cup size is correct (TECH FIG 11E).
■ The cup is calibrated with the trial cup or cup inserted (TECH FIG 11F,G).
■ The cup inserter is navigated to the planned position, and the cup is inserted according to the manufacturer's
recommendations until correct cup placement has been achieved (TECH FIG 11H).

- The cup should be positioned using the anatomy as a reference and aligned with the bone.
- To verify cup position, the pointer is used to acquire four or five points along the margin of the cup (TECH FIG 11I).
- The navigation screen shows various values for the position of the cup implant (TECH FIG 11J).
- Once cup verification has been finished, the pelvic reference array, bone fixator, and two pins are removed, and femoral preparation proceeds.

### Acquiring Femoral Landmarks

- For femoral pin insertion, two pins are inserted to the lesser trochanteric area (TECH FIG 12A).
- The location of the pins varies. They can be inserted into the proximal diaphyseal area, but the lesser trochanteric area is more comfortable and requires a smaller incision.
- Once two pins have been inserted, the bone fixator and femoral reference array are attached (TECH FIG 12B).
- Before starting registration, as many osteophytes are removed as possible, because the presence of osteophytes will affect the femoral notching calculation.
- The first step in femur registration is marking of the medial and lateral epicondyles using a sterile pointer (TECH FIG 12C,D). The pointer then is held to the piriformis fossa and head-neck junction (TECH FIG 12E,F).
- To acquire femoral head points, the pointer is slid across the surface of the bone following the navigator’s direction (TECH FIG 12G,H).

**TECH FIG 12 • A.** The fixation pin is inserted to the lesser trochanter using an automated drill at low speed. The second pin is inserted in the same manner using a drill template. The fixation pins should be placed bicortically for stability. **B.** Once the second fixation pin has been inserted correctly, the bone fixator is attached and the femoral reference array connected to it. Sufficient space should be available to facilitate drilling, reaming, and implant positioning without moving the reference array. **C,D.** Medial and lateral condyle points are acquired using single landmark acquisition. Each point is acquired by holding the tip of the pointer to the surface of the skin at the required location. **E,F.** Acquiring a point on the piriformis fossa. This point is essential for navigation to define the proximal endpoint of the shaft axis. If this point is not defined correctly, the calculated neck axis and implant position may not be accurate. (continued)
Once the femoral head points have been acquired, points are acquired on the anterior, superior, posterior, and inferior neck in sequence (TECH FIG 12, J).

Finally, it is necessary to ensure that there are sufficient points in the most critical area of the bone, where notching is more likely to occur (TECH FIG 12, K, L).

Once registration has been accomplished, a three-dimensional bone model is made on the navigation monitor based on the points acquired (TECH FIG 12, M).

Once the bone model has been made, registration of the femur is verified (TECH FIG 12, N, O).

The current neck–shaft angle (ie, varus or valgus, anteversion or retroversion) and calculated inner diameter of

TECH FIG 12 • (continued) G, H. Acquiring points on the femoral head. To acquire points, the pointer is simply slid across the surface of the bone. This step is important for precise morphologic estimation and for determining the center of rotation and the required implant size. I, J. Acquiring points on the anterior, superior, posterior, and inferior neck. These points are used for estimating the neck axis and required implant size and for generating the femoral bony model. K, L. Acquiring points in the superior notching zone. This step is used to ensure that sufficient points have been acquired in the most critical area of the femur, where notching is most likely to occur. M, N, O. Once the bone model has been calculated, the femoral registration is verified. P. After verification of the femoral model, the current neck–shaft angle is shown automatically, and the surgeon can adjust the angle if necessary. Q. The size of the femoral component is calculated automatically, and the position of the component is planned per the surgeon’s request.
The drill guide pin is moved along the varus-valgus axis and along the antegrade–retrograde axis. The drill guide pin then is relocated to the entry point selected following the navigation system so that it will not result in femoral notching (TECH FIG 13A,B). Once the final adjustment has been made, drilling begins via the centering guide pin, and femoral notching is rechecked using a stylus (TECH FIG 13C,D). Once the hole is successfully drilled and the implant positioned, femoral verification is undertaken (TECH FIG 13E,F). The remaining procedures for femoral component are done in the same manner as those for conventional resurfacing procedures described earlier.
### PEARLS AND PITFALLS

| Acetabular position | - Retract the femoral head sufficiently anterior to the acetabulum to provide a better view and to prevent unequal acetabular reaming or malposition of the component when the impactor handle meets the protruded anterior Hohmann retractor and femur.  
  
- Because the acetabular component has no screw holes, and the inner surface consists entirely of polished area, the surgeon cannot see the inner acetabular surface during insertion of the acetabular component.  
  
- Furthermore, when acetabular osteoporosis is present, the surgeon should be careful to obtain a secure fit of the acetabular component, because additional screw fixation is impossible.  
  
- To prevent under-seating of the acetabular cup, put the trial cup into the fully reamed acetabulum first and check the relation between the peripheral rim of the trial and the acetabulum. Then, when the cup is fully seated in the acetabulum, insert a real cup seated at the same depth as the trial.  
  
- I prefer to use a 1-mm under-reamer rather than the 2-mm under-reamer to easily achieve a fully seated acetabular cup. |
| Prevent femoral notching | - Thorough preoperative templating to determine the ideal inlet point for the femoral guide pin is mandatory.  
  
- Avoid extreme valgus position of the femoral component.  
  
- Do not ream the entire femoral head all the way to the distal rim of the femoral head.  
  
- Use a rongeur to carefully remove any remaining distal rim of the femoral head to prevent further damage to the cervical blood supply and possible notching by a motorized reamer.  
  
- Check notching with the stylus several times during femoral preparation, especially in the anterior and superior portion of the femoral head, which is the most vulnerable for notching.  
  
- The patient must use crutches and then a cane to support weight bearing for 2 months to resist mechanical stress and permit femoral neck remodeling. |
| Femoral component seating | - Use a custom-made femoral trial before insertion of the real component and check the relation (gap) between the lower peripheral margin of the trial and the distal rim of the femoral head when the trial is fully seated. Then insert a real femoral component of the same depth as the trial.  
  
- Insert the femoral component before the “dough” stage of cement is finished; cement that is too hard may prevent the femoral component from being seated. |
| Femoral side first? | - **Pros:** Retracting the femoral head for acetabular preparation is relatively easy, because the femoral head is smaller after femoral preparation.  
  
- If the femoral head is not fit for resurfacing after preparation, the surgeon’s preferred conventional THA can be used.  
  
- **Cons:** A mismatch between the acetabular and femoral components can develop after femoral preparation.  
  
- An already prepared, mainly cancellous, femoral head may be damaged during retraction. |
| Acetabular side first? | - **Pros:** Avoid mismatch between acetabular and femoral components. Acetabular cup size dictates the femoral component size.  
  
- **Cons:** It is not easy to obtain sufficient anterior retraction of the whole femoral head during acetabular preparation.  
  
- If, after preparation, the femoral head is not suitable for resurfacing, a modular, large-head, metal-on-metal THA should be performed, regardless of the surgeon’s preference. |

### POSTOPERATIVE CARE

- The patient receives a second-generation cephalosporin before anesthesia induction and for 48 hours postsurgery.  
  
- An antithromboembolic stocking is applied immediately after the operation to prevent deep vein thrombosis and permit mobilization on the first day after the operation.  
  
- Coumadin can be administered for several weeks for medical prevention of deep vein thrombosis.  
  
- Various protocols for rehabilitation may be followed.  
  
- We continue partial weight bearing with crutches for 4 to 6 weeks to allow initial bony ingrowth on the acetabular side and to allow the patient to regain normal gait and balance.  
  
- To allow femoral remodeling around the neck area, we usually recommend that the patient use a cane until the end of the second month after the operation, after which full weight bearing is permitted. Light sports activity may begin no sooner than 3 months after the operation, after which the patient may even squat on the floor.  
  
- Patients are allowed to ride in a car as a passenger, drive a car, sleep on their side, or engage in any activities if able and so desired.  
  
- Regular sports activities are allowed after 6 months.  

### OUTCOMES

- Daniel and McMinn reported on the results of metal-on-metal resurfacing in patients younger than 55 years with hip osteoarthritis.  
  
- 446 resurfacings were performed in 384 patients, with a maximum follow-up of 8.2 years (mean 3.3 years).  
  
- Of the remaining 440 hips, there was only one failure (0.02%), giving a survival of 99.8%.  
  
- 31% of the men with unilateral resurfacings and 28% with bilateral resurfacings could do heavy or moderately heavy jobs; 92% of men with unilateral resurfacings and 87% of the whole group could participate in leisure-time sports activity.  
  
- DeSmet reported on a Belgian experience of hip resurfacing.
Of 1114 resurfacings performed between 1998 and 2004, the author presented a consecutive series of 252 patients with a follow-up of 2 to 5 years (mean 2.8 years).

Three failures required revision or reoperation: one femoral neck fracture (at 3 weeks); one progressive avascular necrosis of the femoral head that failed at 2 years; and one low-grade infection leading to failure at 2 years.

Two traumatic dislocations were incurred by an inebriated patient; these were reduced without anesthesia.

Sixty-one percent of patients could perform regular strenuous activities.

Nineteen percent of the patients experienced a clicking, locking, or clunking noise or feeling in the first 6 months after surgery, but it was painless and disappeared gradually.

Lilikakis and Villar reported the results of uncemented resurfacings with a hydroxyapatite-coated femoral implant with a minimum of 2 years of follow-up.

Seventy resurfacings were done in 66 patients.

At a mean of 28.5 months of follow-up, the overall survival rate of the prosthesis was 97.1%; the survival rate of the femoral component alone was 98.6%.

Itayem et al.11 used radiostereophotogrammetric analysis to study the stability of 20 resurfacing arthroplasties over a follow-up period of 20 months.

This analysis found no evidence of excessive early migration or loosening of the components.

Yoo et al.16 prospectively investigated the effect of resurfacing arthroplasty on the bone mineral density (BMD) of the femur by comparing 50 patients with hip resurfacing to 50 patients with uncemented THA.

The resurfacing patients demonstrated BMD loss of 2.6% in Gruen zone 1 and 0.6% in zone 7, whereas the THA patients had BMD loss of 7.8% in Gruen zone 1 and 7.7% in zone 7 at 1 year after surgery.

On the acetabular side, the resurfacing patients demonstrated BMD loss of 8% in Delee and Charnley zone 1 and 17.5% in zone 2, whereas the THA patients had BMD loss of 9.8% in zone 1 and 22.3% in zone 2. These results suggest that the hip resurfacing system transfers load to the proximal femur in a more physiologic manner than conventional long-stem devices, that it may prevent stress shielding, and that it preserves the bone stock of the proximal femur.

Shimmin and Back14 carried out a national review of fractures associated with Birmingham Hip Resurfacing systems implanted between 1999 and 2003 in Australia.

3497 Birmingham hips were inserted by 89 surgeons.

Fracture of the neck of the femur occurred in 50 patients, an incidence of 1.46%.

The relative risk of fracture was higher for women than for men.

The mean time to fracture was 15.4 weeks, and it often was preceded by a prodromal phase of pain and limping.

Significant varus placement of the femoral component, intraoperative notching of the femoral component, and technical problems were the common factors in 85% of cases.

Amstutz et al.1 presented their experience with femoral neck fractures that occurred after metal-on-metal hybrid surface arthroplasty.

In a series of 600 resurfacings, five femoral neck fractures occurred (incidence 0.83%).

Four of the fractures occurred in the first 5 months after surgery.

All five fractures were associated with structural or technical risk factors, which may have weakened the femoral neck.

We suggest avoiding or minimizing notching of the femoral neck by performing the cylindrical reaming at the recommended angle of 140 degrees and by stopping reaming before the reamer touches the lateral cortex.

**COMPLICATIONS**

- Femoral neck fracture
- Neck notching (impingement)
- Neck narrowing
- Femoral loosening
- Femoral head collapse
- Acetabular loosening
- Stem tip condensation
- Metal hypersensitivity
- Metal ion release into the bloodstream
- Infection
- Femoral/sciatic nerve palsy
- Deep vein thrombosis
- Dislocation
- Heterotopic ossification
- Spur formation

**REFERENCES**

DEFINITION

- Femoral neck fractures are classified according to the Garden classification11 (Table 1).
- Further simplification of this classification divides these fractures into displaced versus nondisplaced fractures. Guidelines for treatment of nondisplaced femoral neck fractures are beyond the scope of this chapter.
- The indications for a hemiarthroplasty of the hip include displaced femoral neck fractures and salvage for massive acetabular osteolytic defects in revision hip replacement.
- Published reports suggest that bipolar hemiarthroplasty has poor outcomes when used as a primary prosthesis for failures with degenerative joint disease, and this technique currently is not recommended.
- The two types of hemiarthroplasty implants are the unipolar type (eg, Austin-Moore; FIG 1A), and the bipolar type (FIG 1B).
- The bipolar prosthesis has been favored because of its theoretical reduction of wear on the acetabular side, because motion between the inner and outer heads of the prosthesis leads to less motion at the acetabulum–implant interface.15

ANATOMY

- The neck–shaft angle is about 130°/7 degrees in adults and does not vary significantly between genders.
- The femoral neck is anteverted 10.4°/6.7 degrees with respect to the femoral shaft in Caucasians.
- Some ethnic groups (eg, Asians) have a propensity for higher degrees of anteverision, up to 30%.
- Femoral head diameters range from 40 to 60 mm.
- Femoral neck length and shape vary considerably.
- In cross section, the femoral neck is cam-shaped, with a shorter anteroposterior than mediolateral diameter.
- The calcar femorale is a condensed, vertically oriented area of bone that originates superiorly toward the greater trochanter and fuses with the cortex at the posterior aspect of the femoral neck.
- The major vascular supply of the femoral head comes from the lateral epiphyseal branch of the medial femoral circumflex artery.

PATHOGENESIS

- In elderly persons, a femoral neck fracture usually is the result of a fall.
- Several mechanisms have been proposed:
  - A direct blow to the lateral aspect of the greater trochanter
  - A sudden increase in load with the head fixed in the acetabulum along with a lateral, rotatory force. This causes impaction of the posterior neck on the acetabulum.
  - Completion of a fatigue fracture that precedes and causes a fall
  - The incidence of femoral neck fractures increases as bone density falls to osteoporotic levels.
- Femoral neck fractures in young patients typically are the result of high-energy mechanisms.
- The mechanical explanation is axial loading of the distal femur or the foot if the knee is extended.
- The amount of bony displacement and associated soft tissue injury can be much higher.
- Displacement of a femoral neck fracture can lead to disruption of the vascular supply of the femoral neck.
- This vascular compromise may contribute to the high incidence of avascular necrosis (AVN) with this injury.
- If femoral neck fracture occurs, the intraosseous cervical vessels are disrupted.
- The risk of AVN generally corresponds to the degree of displacement of the fracture of the femoral neck on initial radiographs.

FIG 1 • A. Austin Moore prosthesis. B. Cemented bipolar prosthesis.
In displaced fractures, most of the retinacular vessels are disrupted. Femoral head blood supply is then dependent on remaining retinacular vessels and those functioning vessels in the ligamentum teres.

The role of early fixation and joint capsulotomy in prevention of AVN remains controversial.

The incidence of nonunion following a displaced fracture is as high as 60% with nonoperative treatment in some reports.

Femoral neck fractures can be divided into subcapital, transcervical, and basicervical types, based on the location of the injury.

Basicervical fractures often can be treated in a manner similar to intertrochanteric fractures with regard to fracture fixation (FIG 2).

**NATURAL HISTORY**

- Femoral neck fractures are most commonly seen in patients over the age of 50 years.17
- Patients with a single femoral neck fracture have an increased risk of sustaining a second hip fracture.
- Bateman3 and Gilberty12 reported the use of a bipolar prosthesis.
  - The rationale was that less erosion and protrusion of the acetabulum would occur because motion is present between the metal head and polyethylene socket, inner bearing.
  - Acetabular wear is diminished by reduction of the total amount of motion that occurs between the acetabular cartilage and metallic outer shell with interposition of the second low-friction inner bearing within the implant.
  - Overall hip motion also may be greater, because of the compound bearing surface.
  - Barnes et al1 showed that mortality in the first month postoperatively was substantial: as high as 13.3% in men and 7.4% in women.
  - More importantly, delaying surgery beyond 72 hours led to a substantial increase in mortality rate.
  - Factors influencing mortality in cemented bipolar hemiarthroplasty include cardiac history, residence in a nursing home, chronic pulmonary disease, elevated serum creatinine, pneumonia, history of myocardial infarction, duration of surgery, and gender.10
  - Associated injuries may include subdural or epidural hematoma and ipsilateral upper extremity injury for low-energy fractures.

- High-energy fracture patterns have a higher incidence of associated injury, including closed head injury, pneumo- or hemothorax, spinal fracture, visceral injury, and ipsilateral lower extremity bony injury.7

**PATIENT HISTORY AND PHYSICAL FINDINGS**

- A complaint of groin, proximal thigh, or, rarely, lateral hip pain following a fall in an elderly patient should raise suspicion for a low-energy femoral neck fracture.
- Finding a demented patient down on the floor and unable to ambulate also should raise suspicion for a femoral neck fracture.
- The patient’s preinjury ambulatory status must be ascertained when the history is taken. His or her preoperative activity level can help determine the most appropriate type of surgical management.
- Care must be taken to evaluate other possible sources of injury about the hip as well as associated ipsilateral injury.
- Pelvic fracture: Associated injury to the pelvic rami is common. Radiographs are useful in diagnosing these associated injuries.
- Acetabular fracture: In a low-energy injury, acetabular fracture is an uncommon association with a femoral neck fracture. This, however, is not the case in high-energy injury patterns. Thin-slice CT may be useful for diagnosing this injury.
- Inter- and subtrochanteric fracture: Injury to the intertrochanteric area is commonly seen about the hip in elderly patients. Subtrochanteric fractures are less common. Usually, the limb is held in extension, not in a flexed, externally rotated position. Radiographs again are useful for establishing the diagnosis.
- A thorough physical examination should include:
  - Observation of the lower extremity. If it is shortened, externally rotated, and painful to move, a joint effusion secondary to fracture hematoma is most likely responsible, which increases the available space in the joint capsule.
  - Logroll maneuver, which is the most sensitive physical finding. A positive result elicits pain at the groin due to the side-to-side movement of the lower extremity, which creates shear forces across a femoral neck fracture, leading to exquisite pain.
  - Axial load test, which is positive if the maneuver elicits pain at the groin. This test is less specific than the logroll test.
  - Range-of-motion tests. Pain at endpoints of the range of motion may be the only clue to a nondisplaced occult fracture.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Plain radiographs of the AP pelvis and injured hip should be obtained.
- If possible, the legs should be immobilized in internal rotation for the film.
- A shoot-through lateral radiograph is useful for determining the degree of displacement of the fracture fragment, especially for fractures that appear minimally displaced on an AP view.
- A radiograph taken while applying axial traction is helpful to determine location of the fracture along the femoral neck if
displacement of the fracture fragments obscures view of the fracture pattern.
- CT scanning is useful for identifying nondisplaced fractures when clinically suspected as well as associated injuries. It usually is not employed for an isolated, low-energy femoral neck fracture, however.
- Radionuclide uptake bone scans are helpful in identifying occult femoral neck fractures, but may take up to 72 hours to be apparent on film.
- MRI is more sensitive to identifying occult femoral neck fractures than CT scan or bone scan within the first 72 hours.
- It also is highly sensitive to identifying occult fractures at the ipsilateral intertrochanteric area.

**DIFFERENTIAL DIAGNOSIS**
- Intertrochanteric fracture
- Subtrochanteric fracture
- Pelvic fracture
- Acetabular fracture
- Hip contusion or traumatic trochanteric bursitis

**NONOPERATIVE MANAGEMENT**
- Femoral neck fractures rarely are managed nonoperatively. Both nondisplaced and displaced fracture patterns have better functional and overall outcomes when treated surgically.
  - Nonoperative management may be relatively indicated in the patient with severe medical comorbidities who would be unable to tolerate anesthesia for surgery intervention.
  - Because nondisplaced fractures can be internally fixed with percutaneous techniques under local anesthetic and monitored sedation, nonoperative treatment usually is not indicated for this fracture type.
  - In most cases nonoperative treatment should be limited to initial management of the injury before surgical stabilization.
  - A soft pillow should be placed under the patient’s knee and leg to keep him or her in a comfortable position.
  - All patients with femoral neck fractures should be placed on strict bed rest, with a Foley catheter, and intravenous fluids on admission.
  - Axial traction of the injured lower extremity is contraindicated for femoral neck fractures, because it can increase displacement of the fracture fragments.

**SURGICAL MANAGEMENT**
- The best method of surgical fixation of femoral neck fractures is controversial. The debate between internal fixation versus hemiarthroplasty versus total hip arthroplasty continues and is beyond the scope of this chapter.
- General indications for surgical management using hemiarthroplasty include the older patient with low functional demands, or poor bone quality not amenable to internal fixation.
- Hemiarthroplasty is indicated for patients with displaced femoral neck fractures who meet the following criteria.
  - Reasonable general health
  - Pathologic hip fractures
  - Neurologic diseases including Parkinson disease, previous stroke or hemiplegia, or other neurologic diseases
  - Physiologic age greater than 70 years
  - Severe osteoporosis with loss of primary trabeculae in the femoral head
  - Inadequate closed reduction
  - Displaced fracture
  - Preexisting hip disease on the femoral side, namely osteonecrosis, without any acetabular disease.
  - Contraindications include the following:
    - Preexisting sepsis
    - Young age
    - Failure of internal fixation devices, mainly because of acetabular damage that often occurs in that situation
    - Preexisting acetabular disease. Even patients with normal preoperative cartilaginous space may become symptomatic after about 5 years due to degradation caused by friction between the metal and the acetabular cartilage.
    - Indications for cementing a femoral stem vary from surgeon to surgeon and institution to institution.
    - Primary candidates for this approach are patients with poor bone quality, such as those with a “stovepipe” femur or Dorr type C femur. These patients can be difficult to manage with uncemented implants, because they require either massive, canal-filling, uncemented implants that often produce significant stress shielding of the femur or have proximally filled implants that can make accurate adjustment of limb lengths very difficult.
    - Antibiotic-impregnated cement may be advisable for certain high-risk groups of patients. Some patients, such as those on dialysis, may be more prone to sepsis, so use of antibiotic-impregnated cement should be considered for them.
    - Appropriate antibiotics include tobramycin, vancomycin, cefazolin, and erythromycin.
    - Cemented stems also should be considered for patients with pathologic fractures. For these patients, the use of cement with a bone-replacing prosthesis may be the preferred treatment, regardless of age or bone quality.
    - The first-generation cementing technique involved finger-packing without the use of pressurization and a reduction of porosity. Modern cementing techniques use a medullary brush, a cement restrictor, medullary pulsatile lavage, the insertion of epinephrine-soaked sponges, a reduction of cement porosity (ie, vacuum mixing), cement centralizers, and a cement gun for retrograde cement insertion, after which pressurization can be performed with a surgeon’s gloved finger or, alternatively, with a wedge-shaped pressurization device.
    - Because of the embolic load secondary to pressurization, many surgeons avoid cemented components in patients with a history of cardiopulmonary disease.

**Preoperative Planning**
- It is important for preoperative planning that the preoperative x-rays are reviewed and templated for appropriate size and for fixation.
- Pending those findings, appropriate implant selection should be undertaken as well, whether to proceed with a tapered stem, a fully coated medullary-locking stem, or include a cemented stem.
- The patient should undergo an appropriate preoperative workup including medical, cardiac, and anesthesia evaluations.
  - Banked blood should also be available.
  - Important preoperative laboratory studies include complete blood counts, electrolytes, and coagulation studies.
  - Additional blood tests could include total protein, albumin, and appropriate liver studies to evaluate overall the patient’s nutritional status.
Positioning
- Patient positioning is important and should be done very carefully.
- General positioning principles include padding all bony prominences, positioning in a stable position for implant placement, and providing a range-of-motion arc so that implant position and stability can be tested intraoperatively.

Supine Position
- Once the patient is adequately anesthetized, he or she is placed in a supine position, which allows for direct measurement of leg length.
- The operating table is placed in a flat position. A bump is placed beneath the sacrum.
- The patient is brought to the edge of the table, so that the operative hip slightly overhangs the edge of the table.
- A sacral pad is constructed of folded sheets and placed directly beneath the sacrum.
- The modest elevation of the sacrum allows the fat and soft tissues from above the trochanter to fall posteriorly away from the incision, thereby minimizing the amount of tissue that must be dissected in a lateral approach.
- It also allows hip stability to be evaluated in extension.
- A footrest is fixed to the operating table, so that the surgical hip is flexed 40 degrees.
- Both arms are placed on armboards secured at 90 degrees of abduction.
- The operating room table is then inclined 5 degrees away from the operating surgeon to improve visualization of the acetabulum.

Lateral Position
- The lateral position is used for a posterolateral approach to the hip and also can be used for an anterolateral approach.
- Once the patient is adequately anesthetized and a Foley catheter is inserted, he or she is placed in the desired position in a gentle, organized fashion.
- The anesthesiologist controls the patient’s head and neck, holding the endotracheal tube securely.
- One surgical team member controls the patient’s hands and shoulders, and another controls the patient’s hips.
- The ipsilateral arm is positioned in no more than 90 degrees of forward flexion and slight adduction.
- An axillary pad is placed by lifting the patient’s chest and positioning the pad distal to the contralateral axilla.
- The contralateral arm must be kept in no greater than 90 degrees of forward flexion.
- Extrremities are padded over all bony protuberances.
- The operating room table must be kept in an absolute horizontal position, parallel to the floor.
- A number of holders can be used to hold the patient in a lateral decubitus position.
- A beanbag can be used, although it is not as rigid as a variety of other holders. The pubis and sacrum must be secured in the holder.
- Placement of the pubic clamp must be done cautiously, with the pad directly against the pubic symphysis.
- Placement of the pad more inferiorly causes occlusion or compromise of the femoral vessels in the opposite limb, which may go unrecognized.
- Placement of the pad superiorly may compromise ipsilateral femoral vessels, and may prevent adequate flexion and adduction of the operated hip.
- A sacral pad is placed over the mid-sacrum. It should be at least 3 to 5 inches away from the most posterior end of the skin incision (FIG 3A).
- When the patient is securely positioned in lateral decubitus, the position of the pelvis is checked, to make sure that it is not tilted in the anteroposterior direction (FIG 3B).
A chest positioner and pillows between the arms are helpful in preventing anterior displacement of the torso. The perineum is isolated using an adhesive U-shaped plastic drape.

**Approach**

Hemiarthroplasty can be performed through a number of different approaches.

- There are four commonly employed approaches to the hip joint:
  - Anterior (Smith-Petersen)
  - This approach uses the interval between the sartorius and the tensor fascia lata.
  - Risks include injury to the lateral femoral cutaneous nerve.
  - Femoral preparation is difficult and may require traction, hip extension, and the use of a hook to deliver the femur anteriorly for preparation.
  - Anterolateral (Watson-Jones)
  - Lateral (modified Hardinge)
  - Posterior (Southern)
  - Choice of approach is highly dependent on surgeon preference.
  - We use a modification of the lateral muscle-splitting approach to the hip, as originally described by Hardinge, and the use of a cementless tapered stem.4
  - A cemented stem can be implanted through a number of surgical exposures.

**LATERAL APPROACH (MODIFIED HARDINGE)**

**Preparation of the Surgical Site**

- Plastic adhesive drapes are used to isolate the operative field from the perineum and adjacent skin.
  - A large U-drape is placed isolating the perineum and abdomen from the hip.
  - A second drape is placed transversely above the level of the iliac crest, completing the isolation of the wound area from the abdomen and thorax.
  - The foot also is sealed, with a plastic 10 x 10 drape isolating the foot above the level of the ankle.
  - The operative field is scrubbed with a Betadine soap, followed by a preparation with Betadine solution and alcohol (TECH FIG 1A).
  - The incision area is dried to allow better adherence of Ioban drapes (3M, St. Paul, MN).
  - The limb is removed from the leg holder, and the surgeon grasps the foot with a double-thickness stockinette.
  - Impermeable drape is placed across of the bottom of the operating table up to the level of the patient’s buttck.

- The stockinette is unrolled to the level of the mid-thigh and secured with a Coban dressing (3M).
- The limb is draped steriley using two full-sized sheets brought beneath the leg and buttock and held above the level of the iliac crest.
- A double sheet is placed transversely across the abdomen above the level of the iliac crest.
- A clean air room is then sealed at the head of the operating table with sterile adhesive drape.
- The hip area is marked using a sterile pen.
- The greater trochanter is outlined.
- The iliac crest and femoral shaft are palpated, and the skin incision, centered over the trochanter and slightly anterior, is drawn with large cross-hatchings (TECH FIG 1B).
- The hip is flexed to 40 degrees and slightly adducted. The foot is placed on the footrest.

**Incision**

- The skin incision is approximately 5 inches in length.
  - The incision is slightly anterior to the apex of the vastus ridge.
  - The length of the incision also depends on the patient’s degree of obesity.
  - The skin incision is taken sharply through subcutaneous tissues down to the tensor fascia lata (TECH FIG 2A).
  - The fascia is exposed to a small degree, just to allow the incision and subsequent closure.
  - Hemostasis is achieved in the subcutaneous tissue with electrocautery and bayonet forceps.
  - The incision through the fascia lata is in line with the skin incision.
  - A scalpel is used to penetrate the fascia lata and allow a safe entrance to the compartments.
  - The incision is continued with the use of heavy Mayo-Noble scissors. It is not undermined beyond the skin incision or distal or proximal to the skin incision (TECH FIG 2B).

**Proximal Dissection**

- More proximally, the fibers of the gluteus maximus muscle are split using firm thumb dissection.
A Hibbs retractor is used to retract the anterior flap of the fascia lata.
Once that is done, the gluteus medius, greater trochanter, and vastus lateralis are clearly visualized.
The abductor mass is split.
The basic premise of the modified Hardinge approach is to develop an anterior flap, composed of the anterior portion of the vastus lateralis, anterior capsule, anterior third of the gluteus medius muscle, and most of the gluteus minimus muscle to allow exposure of the hip joint.

- The muscle split usually is located in the anterior third of the gluteus medius.
- The muscle split is made using electrocautery through the gluteus medius (TECH FIG 3A,B).
- Once the gluteus medius is penetrated, the surgeon encounters a fatty layer, beneath which is found the gluteus minimus.
- The gluteus minimus is isolated, and a more posterior incision is made with the electrocautery through the gluteus minimus and the capsule onto the acetabulum. (TECH FIG 3C).
- A blunt Hohmann retractor is placed posteriorly to expose the gluteus minimus and capsule. The blunt end of the Hibbs retractor is used to retract the anterior aspect of the gluteus medius.
- The capsule then is visualized in the depths of the wound.
  - The capsule is incised parallel to the superior aspect of the femoral neck, and the incision is extended to the bony rim of the acetabulum with care not to damage the labrum.
  - This area is then packed with an E-tape sponge (TECH FIG 3D).

**Distal Dissection**

- Attention is next turned to the more distal aspect of the wound and the vastus lateralis.
- The anterior third of the vastus lateralis is incised longitudinally using electrocautery, beginning at the trochanteric ridge and extending 2 to 3 cm beyond.
- Once this is dissected subperiosteally in the anterior direction, a blunt Hohmann retractor is placed around the femur medially to reflect the vastus lateralis anteriorly.
- An anterior bridge of soft tissue remains along the greater trochanter between the incision in the vastus lateralis and the incision in the gluteus medius and superior capsule. This bridge consists of the anterior fibers of the gluteus medius, minimus, and capsule.
Attention is turned to the acetabulum.

- The first retractor is placed in the anterior acetabulum.
- A small plane is created between the anterior wall of the acetabulum and the anterior capsule using a Cobb elevator.
- A blunt-tip Hohmann retractor is placed in the 12 o'clock position anterior to the acetabulum beneath the capsule.
- An assistant can then easily retract the anterior soft tissues.
- The second spiked Mueller acetabular retractor is placed in the superior aspect of the acetabulum, retracting the superior capsule in the cranial direction.
- The retractor is placed at 10 o'clock for the right hip and 2 o'clock for the left hip.
- The exact placement of the retractor is outside the labrum and inside the capsule.

- This bridge is incised through the tendon in a gentle arc along the anterior aspect of the greater trochanter, connecting the incisions.
- Healthy soft tissue must be present on both sides of this arc to allow effective repair during closure.
- The bridge is dissected using electrocautery, in the anterior aspect of the greater trochanter, to develop a flap in continuity consisting of the anterior portion of the gluteus minimus and going around the gluteus medius, anterior hip capsule, and gluteus minimus. This exposes the femoral neck and head.
- The dissection is carried medially until the medial aspect of the neck is exposed (TECH FIG 4).
- Exposure usually is adequate to allow for dislocation of the hip, femoral neck, or proximal femur.
- A bone hook is placed around the neck of the femur anteriorly, and the leg is externally rotated to allow for dislocation of the hip, i.e., the hip is placed in the figure-4 position.
- At this point, with a femoral neck fracture, the proximal femur often will dissociate from the femoral neck.
- An initial rough cut of the femoral neck can be performed in line with appropriate preoperative templating.
- Two blunt-tip retractors are placed around the femoral neck to protect the soft tissues.
- Electrocautery is used to mark the femoral neck, and an initial cut of the femoral neck is made with an oscillating saw.

**Placement of Acetabular Retractors**

- Using the impactor mallet, the surgeon drives this retractor into the ilium in a slightly cranial direction.
- The tip is not driven perpendicular to the axis of the body, because it may perforate the dome of the acetabulum.
- To facilitate appropriate exposure prior to placement of the third retractor and to allow posterior mobilization of the proximal femur, a medial capsular release must be performed.
- A curved hemostat is placed between the iliopsoas and capsule, anterior and in line with the pubofemoral ligament.
- The capsule is incised medial to lateral, thereby increasing the mobilization of the femur in a posterior direction.
- A third, double-angled acetabular retractor is placed inferiorly.
- It is placed in the ischium inferiorly, with the blade of the retractor resting on the neck of the femur rather than on the cut surface.

**Femoral Head Removal and Implant Sizing**

- At this point, the femoral head and neck are clearly visualized in the acetabulum.
- The femoral head and neck fracture can be removed using a corkscrew in combination with a Cobb elevator or a tenaculum.
- This should be done carefully so as not to damage the acetabular cartilage or the labrum (TECH FIG 5A,B).
- Once the femoral head is removed, it should be measured to enable the surgeon to estimate the size of the acetabulum.
- The acetabulum should be sized with a trial bipolar or unipolar component to ensure that there will be good fit without overfilling the acetabulum.
- This can be achieved with a good suction-tight feel with placement of the trial component.
- It should move freely without resistance.
- If it floats freely in the acetabulum, the trial component is undersized (TECH FIG 5C).

**Femoral Reaming**

- The femur is exposed with the use of two double-footed retractors, one beneath the greater trochanter and a second retractor medially in the area of the calcar.
- The leg is placed in a figure-4 position, crossed over the opposite thigh.
- The femur should be easily exposed.
- If there is difficulty in this exposure, the leg should be placed in a greater degree of figure-4 and rotation.
- Excess soft tissue is removed from the tip of the greater trochanter to allow for reaming and broaching. This will prevent varus positioning of the component.
- A large rongeur is used to open the femoral canal slightly.
- A small, straight curette is introduced into the femoral canal in neutral orientation.
- The second assistant should use his or her hand to create a target at the distal femur in line with the femur.
- As the surgeon is placing the small curette, he or she can use the opposite hand on the patient’s knee to
■ The femoral broach is introduced in neutral position, and neutral version of the rotation is judged in relation to the position of the knee.
■ Broaching is begun with the smallest broach and then increased until appropriate fit and fill is achieved. This can be gauged by preoperative templating and tactile feedback.
■ The broach is then introduced each time to its full depth.
■ If significant resistance is met, broaching should continue with a series of small inward and then outward taps.
■ Broaching is continued until full cortical seating has been accomplished. This is indicated by an upward change in pitch as the broach is being seated.
■ Final seating and sizing is determined by pitch, tactile feedback, and lack of progression (TECH FIG 7A).
■ Once the final seating of the femoral broach is accomplished, an initial reduction with the appropriate-sized hemiarthroplasty bipolar or unipolar trial component is performed (TECH FIG 7B).

**Femoral Broaching**

- The femoral broach is introduced in neutral position, and neutral version of the rotation is judged in relation to the position of the knee.
- Broaching is begun with the smallest broach and then increased until appropriate fit and fill is achieved. This can be gauged by preoperative templating and tactile feedback.
- The broach is then introduced each time to its full depth.
- If significant resistance is met, broaching should continue with a series of small inward and then outward taps.
- Broaching is continued until full cortical seating has been accomplished. This is indicated by an upward change in pitch as the broach is being seated.
- Final seating and sizing is determined by pitch, tactile feedback, and lack of progression (TECH FIG 7A).
- Once the final seating of the femoral broach is accomplished, an initial reduction with the appropriate-sized hemiarthroplasty bipolar or unipolar trial component is performed (TECH FIG 7B).
Part 3 ADULT RECONSTRUCTION • Section I HIP RECONSTRUCTION

Evaluation of Trial Prosthesis

- The hip is reduced for evaluation.
  - Hip stability is evaluated in full flexion and in internal and external rotation.
  - One finger is kept in the joint to evaluate for anterior impingement.
  - Anterior stability is evaluated with external rotation, adduction, and extension.
  - Leg lengths are measured directly.
  - The position of the pelvis, shoulders, and the knees must be evaluated as the assistants help with orientation (TECH FIG 8).
- Stability also is evaluated with a longitudinal shuck test, with a goal of 1 or 2 mm of shuck.
- Excessively tight soft tissues about the hip cause difficult or incomplete extension of the hip; excessive laxity leads to increased shuck.
- For inadequate soft tissue tension and appropriate leg-length restoration, a lateral offset also can be used.
- It is important to achieve stability, which takes precedence over leg length.

Placement of the Femoral Stem

- Once stability is satisfactory, the trial components are removed.
  - The wound and the femur are irrigated with pulsatile lavage.
  - Excessive debris is removed.
  - The femur is prepared again, with the curette only, to clear any soft tissue debris from the lateral aspect of the femur.
  - The femoral canal must be copiously irrigated.
  - The surgeon and assistant change outer gloves.
  - The appropriately sized femoral component is placed in the femoral canal with the use of an impactor.
  - Varus positioning must be avoided. It can be prevented with appropriate valgus positioning of the stem on insertion, with attention also paid to maintaining the appropriate version.
  - The femoral component is seated into position using firm taps with a mallet.
  - A pause between taps may allow some plastic deformation of the femur.
  - Final seating is determined in relation to the last broach, tactile feedback, pitch change, and lack of progression (TECH FIG 9).

Completion of Implant Placement

- Once the stem is placed, a second trial reduction can be performed with the trial next segment and trial bipolar shell, or a final component can be placed if the broach and stem achieve the same position.
  - If the trial bipolar shell is desired, trial reduction is performed again.
  - The reduction is performed with the patient held in position by the second assistant and the first assistant.
  - The surgeon reduces the hip with distraction, internal rotation, and adduction.
  - The surgical technician can assist the reduction with longitudinal traction.
  - The bipolar is assembled on the back table with the outer acetabular bipolar shell impacted on the appropriate size head.
  - This can be a 22-, 28-, or 32-mm head, depending on the implant system, with a polyethylene insert and bipolar shell that sits over that (TECH FIG 10A).
- Once that is assembled on the back table, the trunion is cleaned and dried, and the bipolar shell is then impacted on to the trunion of the neck of femoral prosthesis.
Once the hip abductor is adequately repaired, the tensor fascia lata is approximated with absorbable sutures in figure-8 fashion.

- This must be done to both the proximal and distal extents of the fascia lata.
- The potential dead space is then obliterated with heavy absorbable sutures, and then smaller, absorbable 2-0 sutures are placed in subcutaneous tissue (TECH FIG 11B).
- Skin staples are applied.
- Sterile dressing is applied with Microfoam surgical tape (3M, St. Paul, MN).
- An abduction pillow is placed between the legs and loosely secured.
- The patient is awakened from anesthesia and brought to the recovery room if, or as soon as, his or her condition is stable.
- Postoperative radiographs are taken in the recovery room (TECH FIG 11C).

The acetabulum is checked one last time before final reduction for any debris or any soft tissue (TECH FIG 10B).

Once it is checked and cleared, the hip is reduced, and the bipolar shell is reduced and checked for appropriate position, after which the wound is thoroughly irrigated and copiously irrigated with pulsatile lavage (TECH FIG 10C).

At this point, drains can be used according to the preference of the surgeon. We prefer not to use drains.

**Wound Repair and Closure**

- The abductor mass is then repaired.
- The vastus lateralis is repaired to the remaining tissue sleeve with interrupted absorbable sutures in figure-8 fashion with no. 1 Vicryl.
- The gluteus medius tendon and capsule are repaired to the tissue sleeve on the bridge of the trochanter.
  - This is done with heavy absorbable sutures in figure-8 fashion.
  - The repair is done at the corner of the gluteus medius tendon and then extended into the proximal split with simple sutures (TECH FIG 11A).

---

**TECH FIG 11** • A. Repair of the abductor mass. B. Repair of the tensor fascia lata. C. AP radiograph of an implanted bipolar prosthesis.
Incision and Dissection
- Exposure of the hip begins with appropriate identification of the bony landmarks.
  - The posterolateral corner of the greater trochanter and the anterior and posterior borders of the proximal femoral shaft are marked 10 cm below the greater trochanter (TECH FIG 12A,B).
  - The incision begins at this point and extends obliquely over the posterolateral corner of the greater trochanter, continuing proximally, so that the acetabulum is centered in the incision.
  - The incision usually is 15 to 20 cm, although this will vary, depending on the patient’s body habitus (TECH FIG 12C).
- Once the subcutaneous tissue is divided, the fascia lata is identified and incised in line with the incision.
- The fibers of the gluteus maximus belly are bluntly separated with firm finger pressure (TECH FIG 12D,E).
- A Charnley self-retaining retractor is placed to retract the gluteus maximus and tensor fascia. The gluteus maximus tendon may be released from the femur.
- The hip is internally rotated to offer exposure to the posterior structures.
- The piriformis tendon is identified by palpation, and a curved retractor is placed deep to the abductors just superior to the piriformis (TECH FIG 12F).
- A cobra retractor is then placed inferiorly, inferior to the femoral neck.
- The short external rotators and piriformis may be released separately from the capsule and tagged.
- The piriformis and conjoint tendons should be divided as close to their insertions as possible.
- Alternatively, the external rotators and capsule can be taken down as one continuous sleeve off the trochanter and femoral neck (TECH FIG 12G).

TECH FIG 12 • A. Palpation of bony landmarks for posterior approach. This is created by the midpoint of the anterior superior iliac spine and the ischial tuberosity. B. Incisional line. Note its placement with respect to the axis of the femur, the proximal extent of the greater trochanter, and the previous line created by bony palpation. C. Skin incision. D. Identification and incision of the tensor fascia lata. E. Exposure of the deep posterior structures of the hip after blunt separation of the gluteus maximus. F. Deep posterior structures of the hip. G. Reflection of the short external rotators. (A–E, Courtesy of Norman A. Johanson, MD.)
Following the reflection of the short external rotators, the capsule is isolated by repositioning the superior and inferior retractors.
- The curved superior retractor is placed deep to the gluteus minimus just over the superior femoral neck and capsule.

Site Preparation
- A capsulotomy is performed from this posterosuperior acetabulum and continued to the tip of the trochanter in line with the posterior border of the abductors.
- It is continued inferiorly along the femoral neck instead of making oblique posterior limit of the capsulotomy in favor of reflecting this capsule as continuous sleeve to the level of the lesser trochanter (TECH FIG 13).
- The quadratus femoris can be released along with the capsule leaving a small muscular cuff with later reattachment. The capsule can be tagged with a suture.
- The hip is gently dislocated using a combination of flexion, internal rotation, and adduction.
- The leg is held at 90 degrees of internal rotation so that the femoral neck is parallel to the ground.
- At this point, the proximal femur usually dissociates from the femoral neck and head, which often remain in the acetabulum.
- Two retractors can be placed around the proximal femur, and a fresh cut of the femoral neck can be performed with an oscillating saw.
- Alternatively, if this is a low femoral neck fracture, this area can be smoothed with a rongeur and attention turned to the acetabulum.
- At this point, the retractors are placed around the acetabulum. Initially a curved retractor is placed anteriorly, retracting the proximal femur out of the view of the acetabulum.
- The operated extremity is placed in slight flexion, which aids in exposure.
- Occasionally, the reflected head of the rectus femoris must be released.
- A Steinmann pin can be placed in the ilium to reflect the abductors, and a small capsulotomy can be made inferiorty to allow for placement of a cobra retractor deep to the transverse acetabular ligament.
- A bent Hohmann retractor can be placed posteriorly, taking care to first palpate the sciatic nerve to ensure that it is out of harm’s way.
- At this point, the acetabulum is exposed, and the femoral head can be removed again with a corkscrew and a Cobb elevator.
- This step should be done very carefully, to avoid damaging the acetabular cartilage.

Component Placement
- The femoral head is measured. A trial shell can be placed in the acetabulum for appropriate sizing, which is performed as described for the modified Hardinge approach.
- Once an appropriate size has been determined, the leg is flexed and internally rotated to expose the proximal femur.
- The leg is held at approximately 90 degrees of internal rotation and 70 degrees of flexion, bringing the osteotomized neck into the surgeon’s view.
- A trochanteric elevator is placed with the teeth under the anterior aspect of the femoral neck, lifting it out of the wound. This allows for unencumbered preperation of the femoral neck (TECH FIG 14A).
- The femur is then prepared in a fashion similar to that described for the modified Hardinge approach (TECH FIG 14B-F).
- In cases where cemented femurs are preferred, a trial of reduction for leg lengths can be performed, and then a final component can be cemented into place.
- The component must be cemented in the appropriate version, and the neck of the prosthesis must sit on the femoral neck, which can be additionally prepared with a calcar planer.

Completion of the Procedure
- Once the final components are placed and the hip is reduced, two drill holes can be made in the posterior aspect of the greater trochanter for repair of the capsular and short external rotators.
- Once the hip is reduced, two nonabsorbable sutures are placed in the capsular flap.
- The capsular and external rotator tagging sutures are then brought through the drill holes and the greater trochanter tied in layers.
- The quadratus femoris and gluteus maximus tendon also can be repaired if that is the surgeon’s preference (TECH FIG 15).
- Subsequently, the Charnley retractor is removed, and the tensor fascia lata and gluteus maximus fascia are reaproximated.
- Dead space is closed with absorbable sutures in the subcutaneous fat, and then absorbable sutures are placed in the subcutaneous tissue.
- Skin staples are applied at the skin level, and a sterile compressive dressing is applied.
- The hip must be held in abducted position. An abduction pillow is placed, and the patient is taken from the lateral position and placed in the supine position at the end of the operation.

TECH FIG 13 • Exposure of the hip capsule. (Courtesy of Norman A. Johanson, MD.)
The trochanteric fossa is cleared of soft tissue, and a pilot hole is made in it with a small metal curette. An entry reamer is inserted along this pilot hole to seek the long access of the femoral canal. The residual femoral neck is cleared with a rongeur or box osteotome. Sometimes a lateralizing reamer is used to ensure direct access to the femoral canal and minimize the possibility of varus implantation. Broaches often are oversized relative to the final implant size, thereby ensuring a minimum cement mantle all around the implant.

The final broach is determined when it adequately fills the proximal femur; it also serves as a trial component for reduction. Once the stability, limb length, and offset are satisfactory, cementation can be performed. The canal is gently curetted to remove any loose cancellous bone. The canal is irrigated with a long pulsating irrigating tip. High-quality cancellous bone remains in the femoral canal following this preparation. It is important to centralize the prosthesis to ensure an uninterrupted cement mantle around the implant. A plug is placed after the canal is irrigated.
The prosthesis is then inserted into the doughy mass of cement with the centralizer attached to the tip. The leg is placed in a secure position, and the prosthesis is inserted. The prosthesis must be inserted with the appropriate anteversion from insertion all the way down. It is preferred not to rotate the femoral component within the canal, because this will create undesirable cement voids. The prosthesis must be inserted with great care to avoid varus malposition. All the excess cement is then removed, and the stem is held in place until the cement has fully hardened. The femoral trunion should be cleaned at this point, and the hemiarthroplasty component should be inserted onto the stem. The hip is then reduced and the appropriate closure is performed.

We prefer to allow 1 to 2 cm of cement below the tip of the implant so that the plug may be placed at that level. It must be secure enough to withstand pressurization. Three 40 gram packs of cement are typically mixed with a vacuum system. The canal is then packed with sponges to keep it dry during the cementation. Alternatively, continuous suction may be used. The viscosity of the cement is an important consideration. The cement should be somewhat doughy and delivered through a cement gun. Appropriate cement viscosity has been reached when the cement no longer sticks to the surgical gloves. Once the cement reaches the appropriate viscosity, the packing sponges are removed and the canal is suctioned. Cement is delivered in a retrograde fashion into the canal. Once the canal is filled with cement, a pressurizing unit can be placed over the proximal femur, or pressurization can be achieved with a gloved finger.

The prosthesis is then inserted into the doughy mass of cement with the centralizer attached to the tip. The leg is placed in a secure position, and the prosthesis is inserted. The prosthesis must be inserted with the appropriate anteversion from insertion all the way down. It is preferred not to rotate the femoral component within the canal, because this will create undesirable cement voids. The prosthesis must be inserted with great care to avoid varus malposition. All the excess cement is then removed, and the stem is held in place until the cement has fully hardened. The femoral trunion should be cleaned at this point, and the hemiarthroplasty component should be inserted onto the stem. The hip is then reduced and the appropriate closure is performed.

We prefer to allow 1 to 2 cm of cement below the tip of the implant so that the plug may be placed at that level. It must be secure enough to withstand pressurization. Three 40 gram packs of cement are typically mixed with a vacuum system. The canal is then packed with sponges to keep it dry during the cementation. Alternatively, continuous suction may be used. The viscosity of the cement is an important consideration. The cement should be somewhat doughy and delivered through a cement gun. Appropriate cement viscosity has been reached when the cement no longer sticks to the surgical gloves. Once the cement reaches the appropriate viscosity, the packing sponges are removed and the canal is suctioned. Cement is delivered in a retrograde fashion into the canal. Once the canal is filled with cement, a pressurizing unit can be placed over the proximal femur, or pressurization can be achieved with a gloved finger.

ANTEROLATERAL (WATSON-JONES) TECHNIQUE

One major difficulty with the Watson-Jones technique is dealing with the gluteus medius and minimus. The hip abductors lie over anterior hip capsule and could be damaged in an effort to obtain adequate exposure. The original approach used by Charnley placed the patient in a supine position and required a trochanteric osteotomy. This approach is used less commonly now because of problems associated with trochanteric reattachment. The skin incision is made 2.5 cm behind the anterior superior iliac spine to the tip of the greater trochanter, then extended vertically along the anterior margin of the trochanter. The intraneural interval is between the tensor fascia lata and gluteus medius. An incision is made in the underlying iliotibial band, after which the tensor fascia lata is retracted medially and the gluteus medius is retracted laterally. Deep dissection may require release of the anterior parts of the gluteus medius and minimus, which are raised from the femur and retracted posteriorly.

PEARLS AND PITFALLS

<table>
<thead>
<tr>
<th>Acetabular reaming</th>
<th>Not recommended for hemiarthroplasty, because it leads to poor results. Appropriate femoral head size should be chosen intraoperatively to avoid reaming.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Varus malalignment</td>
<td>Care should be taken to broach the lateral cortex of the proximal femur adequately to prevent varus malalignment of the implant.</td>
</tr>
<tr>
<td>Implant orientation (anteversion)</td>
<td>Ideally, the patient's hip should be reoriented to its native position. Ideal anteversion of the hip in adults is 10 to 30 degrees, dependent on multiple patient-specific factors. If the patient has pathology that affects hip orientation (eg, DDH), a modular total hip arthroplasty implant could be considered.</td>
</tr>
</tbody>
</table>
POSTOPERATIVE CARE

- All patients are placed into a soft hip abduction pillow, and bilateral thromboembolic stockings are put on with sequential venous compression devices.
- Antiembolic prophylaxis is started according to the surgeon’s preference.
- Extended prophylaxis may be considered for these patients.

OUTCOMES

- Bipolar hemiarthroplasty was introduced in the 1970s in an effort to prevent or retard acetabular wear.
  - These femoral prostheses have a 22- to 32-mm head that articulates with a polyethylene liner.
  - The liner is covered with a polished metal outer shell that articulates with the acetabular cartilage.
  - Depending on implant design, about 45 degrees of angular motion is available before the prosthetic neck impingements on the liner and axial rotation is restricted.
  - Theoretically, hip motion occurs primarily at the prosthetic joint and only secondarily at the metal-cartilage interface.
  - The polyethylene liner may help to protect the native acetabular cartilage by cushioning the high-contact pressures that occur across the bearing.
  - LaBelle et al.14 reported no acetabular protrusio or articular cartilage wear greater than 2 mm in 49 femoral neck fractures treated with cemented bipolar hemiarthroplasties at 5- to 10-year follow-up.
  - Wetherell and Hinves19 reported a 50% reduction in acetabular erosion for patients treated with a cemented bipolar prosthesis when compared to those treated with a unipolar prosthesis.
  - Research attempting to demonstrate that motion occurs within a bipolar prosthesis has yielded conflicting results.
  - Drinker and Murray9 fluoroscopically evaluated 13 hips in 10 young patients following bipolar reconstruction for AVN and noted that only a minor amount of motion occurred at the inner bearing and that motion tended to decrease over time.
  - They further demonstrated that in this group most implants functioned as a unipolar prosthesis and concluded that motion will occur at the interface where there is the least frictional resistance. They found that this location is not the same in arthritic hips as in fractured hips.
  - These patients with acute hip fracture proved that with normal articular cartilage, primary intraoperative or intraprostatic motion occurred in only 25%, and most implants again functioned as unipolar.
  - Brueton et al.6 whose radiographic analysis of 75 bipolar prostheses, were equally divided between 32-mm and 22-mm heads, showed that the smaller head was associated with more motion.

COMPLICATIONS

- Thromboembolism (eg, deep vein thrombosis, pulmonary embolism)
  - Kenzora et al13 reported a mortality rate of 14% during the first year following hip fracture.
  - When compared to 9% mortality in population of similar age, the mortality after hemiarthroplasty is 10% to 40%.
  - The incidence of intraoperative femur fracture is 4.5%. Most are nondisplaced and involve either the trochanter or calcar.
  - When an intraoperative femur fracture occurs, treatment options include methylmethacrylate combined with long-stem prosthesis or, alternatively, with a fully coated cementless stem and cables.
  - The rate of dislocation is less than 10%. Dislocation is more common with incorrect version, posterior capsulotomy, and excessive postoperative flexion or rotation with the hip adducted.
  - Postoperative sepsis has been reported to range from 2% to 20% and may be more common with the posterior surgical approach. Infections may be superficial or deep.
  - Loosening or migration may be suspected with the presence of a radiolucent line around the prosthesis.
  - If clinical signs and symptoms are present, or loosening or migration is present, a revision arthroplasty may be considered.
  - Cementation does present some hazards, and in some cases the application of pressurized cement is associated with an embolization phenomenon with cement elements (ie, monomer, polymethylmethacrylate elements, or fat). Embolization of these materials may result in hypoxia, cardiac arrest, or death.
  - The risk factors include older age or patent foramen ovale.
  - The use of pulsatile lavage can reduce that risk by removing fat and marrow from the femoral canal.
  - In older patients with substantial medical comorbidity, it may be wise to avoid pressurization of the cement within the canal, because the risk of acute embolization may be high.

REFERENCES

Metastatic bone disease (MBD) afflicts more than half of the 1.2 million patients newly diagnosed with cancer annually.\(^3\)\(^,\)\(^5\) Bony involvement can be a major source of morbidity and mortality if not treated appropriately. The femur is the long bone most commonly affected, with 25% involving the proximal third of the femur.\(^3\)\(^,\)\(^13\)\(^,\)\(^14\) Seventy-five percent of all surgery for cancer that has metastasized to bone is performed in the hip area.\(^14\)

**ANATOMY**

Metastatic foci to any part of the areas around the hip substantially compromise the mechanical integrity of the bone, placing the patient at high risk for fracture and subsequent nonunion. The bony structure of the acetabulum consists of the anterior and posterior columns with their respective walls, which jut over laterally to cover the femoral head. The anterior column is defined as the bone that extends from the iliac crest to the pubic symphysis. The posterior column starts from the articulation of the superior gluteal notch with the sacrum and extends through the acetabulum and ischium to the inferior pubic ramus. The acetabular dome, the superior weight-bearing region, consists of both the anterior and posterior columns and is contributed to by both walls. The femoral head is not truly spherical; it is congruent only along the weight-bearing portion. The principal and secondary bony trabeculations of the head, neck, and intertrochanteric area enable the head and neck arcade to withstand tremendous compressive and tensile forces.

**PATHOGENESIS**

The mechanism by which metastases occur is accounted for in a modified “seed/soil” theorem. Fewer than one in 10,000 neoplastic cells that escape into the circulation from the primary site are able to set up a metastatic focus. Metastasis, a complex, multistep process in which the cell first must break free, is a function of degradative enzymes such as collagenases, hydrolases, cathepsin D, and proteases. Once the cell invades the vascular channel, it circulates through the body. It is theorized that the cell is protected by a fibrin platelet clot. Clinical trials with heparin have not shown a significant change in metastatic outcome, however. Local factors such as integrins are instrumental in attracting the circulating metastatic cell to a particular remote tissue site. Once within the new tissue, the metastatic cell releases mediators such as tumor angiogenesis factor, inducing neovascularization, which, in turn, facilitates growth of the metastatic focus.

Patients with advanced metastatic disease often experience dysfunction of hematopoietic and calcium homeostasis. They may develop a normochromic, normocytic anemia with leukocytosis. The increased number of immature cells, produced in response to the anemia and noted on the peripheral blood smear, is termed a leukoerythroblastic reaction. Hypercalcemia may be seen in up to 30% of patients with extensive metastases, most commonly in myeloma, breast cancer, and non–small cell lung cancer. Blastic metastases often are painless and are associated with a lower incidence of pathologic fracture because the bone is not as severely weakened. Not all tumors that metastasize from the prostate to bone are blastic in nature, however. The lytic variants are painful and can cause pathologic fractures.

Most tumors that metastasize from the breast to bone are blastic, but some demonstrate mixtures of blastic and lytic areas in the same bone. By taking serial radiographs and noting the appearance of bone metastases, it is possible to follow the progress of treatment with systemic hormone therapy or chemotherapy agents plus local radiation therapy. A favorable response may show a gradual conversion from a lytic to a blastic appearance as the pain decreases.

Bone destruction in lytic lesions occurs as a result of the biologic response by native osteoclasts to the tumor. Neovascularization is common. Among the tumors that are characteristic for this hemorrhagic response are thyroid carcinomas, renal cell carcinoma, and multiple myeloma. Before surgical intervention is undertaken for these tumor types, it may be beneficial to perform a prophylactic embolization of the area to reduce perioperative bleeding. If a lesion is unexpectedly found to be aneurysmal at the time of surgical exploration, the friable tumor mass should be debulked rapidly down to normal bone, and the area should be packed until it can be stabilized with bone cement.

**NATURAL HISTORY**

Metastatic involvement of the musculoskeletal system is one of the most significant clinical issues facing orthopedic oncologists. The number of patients with metastasis to the skeletal system from a carcinoma is 15 times greater than the number of patients with primary bone tumors of all types. About one third of all diagnosed adenocarcinomas include skeletal metastases, resulting in about 300,000 cases per year. Furthermore, 70% of patients with advanced, terminal carcinoma demonstrate bone metastases at autopsy.

The carcinomas that commonly metastasize to bone are those of the prostate, breast, kidney, thyroid, and lung. One study showed that nearly 90% of patients with these types of carcinoma had bone metastases. Among the carcinomas that less commonly metastasize to bone are cancers of the skin, oral cavity, esophagus, cervix, stomach, and colon.

Because patients with metastatic bone disease are surviving longer, surgeons must strive to perform an optimal reconstruc-
tion that can provide functional outcome for many years. Once a pathologic fracture has occurred, however, a patient’s life expectancy is considerably shorter. Stringent surveillance by medical oncologists for bony metastases must be encouraged, therefore, with early referral to the orthopedic surgeon before pathologic fractures occur.

PATIENT HISTORY AND PHYSICAL FINDINGS
- In any patient with a history of cancer, especially those cancers that are well documented to metastasize to bone, any bone pain should raise suspicion for a metastatic focus.
- Pain at rest or at night that is or is not exacerbated with activity should heighten this suspicion.
- The hip examination may or may not be abnormal.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- A methodical approach is mandatory in the workup of a patient with presumed metastatic disease to bone to locate the primary tumor.
- A thorough history and physical examination must be completed before laboratory and radiographic analyses are done. The primary carcinoma may be detected on physical examination in as many as 8% of patients.
- Laboratory analysis should include a complete blood count, erythrocyte sedimentation rate, renal and liver panels, alkaline phosphate, and serum protein electrophoresis.
- Radiographic examination should follow with a plain chest radiograph and radiographs of known involved bones.
- For metastases to the hip, an anteroposterior radiograph of the pelvis and full anteroposterior and lateral radiographs of the entire femur should be obtained.
- About 45% of all primary tumors will be detected in the lung on the chest radiograph.
- The workup also should include a staging bone scan.
- If this scan is negative, myeloma should be suspected.
- If the scan is positive, a lesion may be found at a more convenient biopsy site.
- Bone scanning is more sensitive than plain radiographs in detecting early lesions.
- CT scans of the chest, abdomen, and pelvis should be performed.
- CT of the lung can detect up to 15% of primary tumors missed on the plain radiograph.
- The use of PET scanning, either in isolation or in conjunction with CT, is becoming more common in the workup of patients with possible metastatic cancer.
- These studies, in combination with a well-planned biopsy, will reveal the primary cancer for most patients.
- Routine radiographic screening studies in search of early metastatic disease are not very helpful. Lytic changes become evident on routine radiographs only when cortical destruction approaches 30% to 50%.
- If a lesion is detected about the hip in the anatomic areas as described earlier, and a detailed pelvic and hip CT has not been performed within the past 6 to 8 weeks, one should be ordered.
- Intravenous contrast medium is not necessary.
- A recent CT scan is particularly important in the preoperative planning for an acetabular reconstruction.

DIFFERENTIAL DIAGNOSIS
- Prostate cancer
- Breast cancer
- Kidney carcinoma
- Thyroid carcinoma
- Lung carcinoma
- Myeloma
- Lymphoma of bone, while less common, can mimic these diagnoses.
- For a patient over the age of 40 years, with no known history of metastatic carcinoma to bone, the osteophilic malignancies mentioned earlier must be considered and evaluated as described.

NONOPERATIVE MANAGEMENT
- Nonsurgical management of metastatic carcinoma to bone includes observation, radiation treatment, and hormonal or cytotoxic chemotherapy.
- Radiation is reserved for palliative intervention. Each patient’s suitability for radiation therapy must be carefully determined. The histologic type of disease, extent of disease, prognosis, marrow reserve, and overall constitution must be assessed.
- Impending lesions about the proximal femur and acetabulum should dissuade the orthopedist from nonoperative management, particularly in renal cell and thyroid carcinoma, where bony destruction is likely to progress despite the best nonsurgical modalities.
- For a patient who has sustained a pathologic fracture secondary to metastatic carcinoma, the average survival time is 19 months.
- Each histologic type has varying lengths of survival: prostate—29 months; breast—23 months; renal—12 months; lung—4 months.
- Moreover, each type of carcinoma exhibits varying radiosensitivity: prostate and lymphoreticular carcinomas, excellent; breast carcinoma, intermediate; and renal and gastrointestinal carcinomas, poor.
- When radiation therapy is used appropriately, 90% of patients gain at least minimal relief, with up to two thirds obtaining complete relief. Seventy percent of patients who are ambulatory retain their ability to ambulate after radiation therapy to the lower extremities.
- Systemic radioisotopes also may be used. Strontium Sr 89 imitates calcium distribution in the body and has shown promise in clinical applications.
- When a patient has sustained a true pathologic fracture (rather than an impending lesion), surgical stabilization usually is indicated, with subsequent radiation therapy. Because of poor bone quality, bone cement often must be used to augment the fixation.
- Hormonal therapy has an important role in the management of metastatic breast and prostate cancer. Fortunately, these agents are easy to administer and have few side effects.
- For breast cancer, medical hormonal manipulation can be done by use of antiestrogens, progestins, luteinizing hormone–releasing hormone, or adrenal-suppressing agents.
- Tamoxifen is effective in 30% of all breast cancer cases; its effectiveness increases to 50% to 75% of cases in which the tumor is known to be estrogen receptor– and progesterone receptor–positive.
Surgical ablation (oophorectomy) also may have a role in certain cases.
In some cases of prostate cancer, reduction in testosterone levels via bilateral orchidectomy or administration of estrogens or antiandrogens may produce dramatic results.
Estrogens are no longer used as a first-line agent because of the risk of cardiovascular complication.
Cytotoxic chemotherapy is used extensively in treatment for adenocarcinoma. In older patients with advanced disease, however, the side effects of the drugs may be too severe.

**SURGICAL MANAGEMENT**

For cases involving the periacetabular area, femoral head, neck, and intertrochanteric area, cemented femoral arthroplasty components are an important surgical option for impending and realized fracture management.
The goals for surgical intervention in the patient with metastatic carcinoma to bone are relief of pain; prevention of impending pathologic fracture; stabilization of true fractures; enhancement of mobility, function, and quality of life; and, for some, improved survival.
It is generally agreed that a patient must have a life expectancy of at least 6 weeks to warrant operative intervention.
Cancer patients, regardless of their age, may have increased difficulty protecting their fixation device or prosthesis secondary to systemic debilitation. Accordingly, rigid fixation, with polymethylmethacrylate (PMMA) augmentation as needed, is mandatory.

**Preoperative Planning**

In many cases, the diagnosis of metastasis to the proximal femur will be made before a fracture occurs. In these cases, it is the responsibility of the orthopedic surgeon to decide whether the patient should receive some form of internal stabilization before radiation therapy is begun. A CT scan of the involved area will help make this decision.

Criteria for the performance of a prophylactic stabilization procedure include the following:
- 50% cortical lysis
- A femoral lesion greater than 2.5 cm in diameter
- An avulsion fracture of the lesser trochanter
- Persistent pain in the hip area 4 weeks following the completion of radiation therapy
- A Mirels score (Table 1) also may help in decision-making for hip and femoral lesions.

As elucidated in the Mirels score, the peritrochanteric area in general is at high risk for fracturing.
These criteria are not perfect, and large errors arise in estimation of the load-bearing capacity of the bone. For example, no system takes into account the histologic subtype, pre-existing osteoporosis, and functional demands. Objective quantification of pain in the Mirels score is controversial as well.

**Periacetabular Lesions and Impending and Realized Fractures**

Class I (minor): lateral cortices, superior, medial wall intact (FIG 1). Treat with conventional cemented acetabular component with or without rebar (anchorage with large fragment screws) as needed.

A mean score of 7 or below indicates a low risk of fracture; radiation therapy should be considered. A score of 8 or above suggests a substantial risk, and surgical intervention is recommended.

**FIG 1** Periacetabular lesions, class I (minor). Depiction of lesion (A) and repair (B). C. Left supracetabular lesion as seen on CT scan. D. Postoperative radiograph demonstrating reconstruction. Steinmann pin augmentation of the anterior and posterior columns was performed.
Class II (major): deficient medial wall (FIG 2) requires an antiprotrusio device, medial mesh, or rebar.

Class III (massive): deficient lateral cortices and dome (FIG 3) mandate rebar augmentation of the posterior and sometimes the anterior columns; 6.5-mm cancellous screws or 5/16-inch Steinman pins are recommended.

Class IV: resection is mandatory for attempted cure. Such cases should be referred to an orthopedic oncologist and are beyond the scope of this chapter.

**Femoral Head and Neck**

- Impending fractures
  - Femoral head involvement is a reason to perform arthroplasty (FIG 4).
  - Modest femoral neck lesions may be stabilized with a reconstruction nail, with the exception of renal cell and thyroid carcinoma, in which cases arthroplasty is recommended.

- Realized fractures
  - Rarely heal

- Internal fixation device failure is common.

- Procedure of choice: replacement arthroplasty
  - The decision regarding bipolar versus total hip arthroplasty is a function of acetabular involvement, preexisting arthritis, and life expectancy.
  - Acetabular disease may go unrecognized on plain radiographs in up to 83% of cases. Pelvic CT is imperative.
Long-stem prostheses may be used for extensive femoral involvement, but attention must be paid to cement deployment during the early cure stage, use of a long laparoscopic sucker, or venting.

**Peritrochanteric Neck**
- Impending fractures
  - An intramedullary reconstruction-type device is strongly recommended. Screw and side plate constructs have a high failure rate (FIG 5A).
  - For renal cell and thyroid cancer, the surgeon should proceed with cemented calcar-replacing arthroplasty.
- Realized fractures
  - Cemented calcar-replacing arthroplasty is the only appropriate option (FIG 5B-E).

**Subtrochanteric**
- Impending fractures
  - With the exception of renal cell and thyroid carcinoma, a cephalomedullary nail reconstruction is appropriate when bone loss is not extensive (FIG 6A-E).
  - Otherwise, proximal femoral replacement is necessary.
- Realized fractures
  - Cemented proximal femoral replacement is the only option.

**FIG 5**
- A. Peritrochanteric metastatic lung cancer treated with screw and side-plate construct that failed within 4 months. For realized and large impending peritrochanteric lesions (B), the surgeon should have a low threshold for replacement arthroplasty (C). D. A realized intertrochanteric pathologic fracture from metastatic breast cancer was inappropriately treated with a reconstruction nail that went on to hardware failure within 3 months. E. The case shown in D was converted to a calcar-replacing hemiarthroplasty.

**FIG 6**
- Subtrochanteric femoral lesion (A) and cephalomedullary nail reconstruction (B). AP (C) and lateral (D) radiographs of an impending peri-subtrochanteric metastasis of breast carcinoma to bone treated with prophylactic stabilization (E). F. A patient with documented metastatic breast cancer to bone presented with a several-week history of progressive aching in the upper thigh. She was walking when she felt a snapping sensation and immense pain and was no longer able to ambulate. G. Treatment was with a proximal femoral replacement.
viable option to restore the patient to ambulatory status (FIG 6F, G).
- Long-stem cemented femoral arthroplasty use in patients with MBD remains controversial. Some surgeons remain trepid in the general use of cemented long-stem femoral arthroplasties in patients with MBD because of the risk of cardiopulmonary insult and collapse.
- Combining the use of bone cement with a long-stem femoral component further increases the possibility of complications, especially in a patient with MBD who has poor-quality bone and severe preexisting medical conditions. Deciding whether femoral stability from a cemented long-stem arthroplasty is worth the increased risk of a life-threatening cardiopulmonary embolic event is difficult. Certain steps listed in the following sections have been shown to minimize this risk, warranting long-stem use in cases of extensive femoral disease.12

Positioning
- Hip arthroplasty can be performed in either the supine or lateral decubitus position, but it is strongly recommended that the patient be placed in the decubitus position for anything other than a routine arthroplasty. This enables the surgeon to perform arthroplasty as well as extensive instrumentation of the posterior column when necessary.
- Reconstruction of impending proximal femoral lesions can be performed with the patient in the supine position, placed on a fracture table that allows insertion of a cephalomedullary device and interlocking screws.

Approach
- Standard, but sometimes expanded, anterior, anterolateral, and posterior approaches may be used to access the acetabulum.
- For posterior column instrumentation, an extensible posterior approach is recommended.

PERIACETABULAR RECONSTRUCTION

- Rigid fixation of the acetabular component is critical to success. The preoperative CT and plain radiographs must be evaluated carefully before surgery (TECH FIG 1A, B).
- Class I defects can be managed with a conventional cemented acetabular component, with or without augmentation of fixation with large fragment screws (TECH FIG 1C–E).
- Class II defects
  - An anti-protrusio cage or a similar device must be used.
  - Any flanges or screws must be attached to healthy bone.

- A posterior approach without a trochanteric osteotomy usually is adequate.
- Nonunion of a trochanteric osteotomy is a major concern in patients with cancer and should be avoided unless absolutely necessary.
- Visualization of the posterior column, however, is critical to confirm its mechanical integrity; therefore, an incision of adequate size must be used.
- Class III defects
  - An extensive posterolateral or lateral approach usually is chosen to deploy 6.5-mm cancellous screws or

TECH FIG 1 • A. AP pelvic radiograph demonstrates a periacetabular metastatic focus. B. CT scan reveals the extent of posterior wall involvement of this class I defect. C, D. Posterior wall/column screws are used to augment the reconstruction. E. The screws are then incorporated in the cement mantle of the acetabular component. F. Intraoperative photos demonstrating adequate positioning of a combination of pins and screws to augment the cement fixation.
Although anterior column fixation is less important than posterior column fixation, if the anterior column is compromised, Steinmann pins may be deployed antegrade from the anterior crest into the acetabular defect.

Some surgeons use targeting jigs, but I prefer to use a careful freehand technique with the nondominant hand in the defect to target the pin.

These anterior pins are cut flush with the crest after they are deployed to the appropriate depth in the defect, ideally capturing the ilium.

With the rebar in place and sunk to a depth that does not interfere with the acetabular component also being sunk to the correct depth, version, and verticality, mesh or similar material is placed to limit cement extrusion.

The acetabular component is then cemented into place, making sure to get the PMMA fully interdigitated with the rebar.

LONG-STEM CEMENTED FEMORAL COMPONENTS

- I prefer to use long-stem femoral components during hip arthroplasty for metastatic bone disease, with a minimum stem length of 300 mm (TECH FIG 2A).
- Various surgical techniques have been proposed to reduce perioperative canal debris or IM pressurization.
- Low-viscosity cement, IM venting, retrograde injection, thorough IM lavage, and intraoperative canal suctioning during cementing may decrease embolic events and decrease perioperative complications.
- Femoral preparation and component placement are performed in a similar systematic fashion.

- After the femoral neck cut is completed with an oscillating saw, the canal is prepared with flexible reaming and broaching.
- The canal is suctioned between subsequent reamers with a long laparoscopic suction device (Conmed Corp, Utica, NY; TECH FIG 2B,C). The canal then is thoroughly brush-lavaged using the Pulsavac (Zimmer, Warsaw, IN) system.
- Three batches of Surgical Simplex P bone cement (Stryker, Mahwah, NJ) are mixed with 3.6 g of tobramycin for femoral cementation because of the
patient’s immunocompromised condition. I prefer Simplex P bone cement because of its low viscous qualities on immediate mixing. Once the cement is mixed (≤ 1 minute), it is immediately injected into the femur in its early, liquefied cure state using a long cement gun.

- The long laparoscopic suction device (Conmed Corp, Utica, NY) is used to aspirate the canal immediately before and during insertion of the PMMA.

### CALCAR-REPLACING HIP ARTHROPLASTY

- In the presence of peritrochanteric bone loss without subtrochanteric extension, a cemented calcar-replacing implant may be used.

### PROXIMAL FEMUR REPLACEMENT

- For proximal femoral replacement, a long posterolateral incision is made to expose the proximal quarter to third of the femur.
  - The iliotibial band is incised longitudinally to permit anterior and posterior exposure.
  - The gluteus maximus is carefully split, with concurrent meticulous ligation of perforating arterioles.
  - Time is taken to localize and protect the sciatic nerve in the retrogluteal area, where it lies immediately behind the external rotators.
  - The abductors are defined, and the greater trochanter is osteotomized and preserved if it is not extensively involved with tumor.
  - If the greater trochanter is too compromised, the abductors are transected at their tendinous attachment.
  - The vastus lateralis muscle is reflected anteriorly, ligating the perforators serially. The main blood supply enters anteriorly.
  - The external rotators are taken down using the surgeon’s preferred standard technique.

- The hip capsule, however, should be preserved as carefully as possible, because it is instrumental in stabilizing the endoprosthetic reconstruction. It is recommended that the capsule be incised longitudinally, with the incision extending anteriorly over the neck, and detached circumferentially.
  - It is strongly recommended that the entire limb, including the foot, be prepped in sterile fashion so that a distal pulse examination may be performed intraoperatively.
  - The hip is dislocated anterolaterally.
  - The acetabulum is inspected and assessed for possible reconstruction.

- Femoral resection level is determined by the lesion or fracture (TECH FIG 3A,B).
  - If the fracture being managed is a realized fracture, a fresh transverse osteotomy should be performed at the level of healthy, uninvolved bone.
  - A malleable retractor is placed medially after the soft tissues have been emancipated with a Cobb or similar elevator.

**TECH FIG 3**

A. Resection of isolated renal cell carcinoma metastasis to the proximal femur. B. The femoral osteotomy is just below the lesion, to provide disease-free bone stock for fixation of the proximal femur replacement. The size of the modular bodies available per the manufacturer is taken into account. C. The modular prosthesis in situ, corresponding to the length of the resected specimen. D. Durable abductor mechanism is critical to functional restoration. I prefer to use a soft tissue washer drilled through any residual greater trochanter that might be available.
Intraoperatively, the surgeon must carefully determine the appropriate version, which is about 95 to 100 degrees off the midsagittal plane as determined by the linea aspera. The prosthetic neck should be angled anteriorly 95 to 100 degrees off this plane.

The prosthesis is assembled as described by the manufacturer.

I strongly recommend against deploying the cement in too viscous a state.

A long laparoscopic-type suction device should be used continously throughout instrumentation of the femoral canal, and consideration should be given to venting if a long stem is to be deployed.

The canal should be brushed as well.

As the cement matures after prosthetic deployment, the surgeon must immediately and carefully confirm the selected version.

Soft tissue reconstruction is of paramount importance for a sound functional result.

The hip capsule should be purse-stringed about the prothetic neck using a no. 5 polyfilament, nondissolving stitch.

Once repaired, it should not be possible to dislocate the hip anteriorly, posteriorly, or laterally.

The tagged psoas tendon may be sewn to the anterior capsule. Likewise, the external rotators may be sewn to the posterior capsule.

At this point, the sciatic nerve is again checked to make sure it is not compromised.

Numerous techniques have been described for reattaching the abductor mechanism to the implant. Vendors also have various capture mechanisms. The surgeon must pay close attention to the reattachment mechanism, because this is the limit of the functional reconstruction.

I prefer to use a soft tissue washer specific to the implant that can either be drilled through the residual trochanteric bone or harness the tendon itself (TECH FIG 3D).

The vastus lateralis muscle is repaired, as are the gluteus maximus and iliotibial band.

For metastatic cases, a drain is not mandatory unless the lesion is highly vascular (eg, renal cell and thyroid).

### PEARLS AND PITFALLS

<table>
<thead>
<tr>
<th>Potential cardiopulmonary collapse secondary to cementation of femoral components</th>
<th>The use of low-viscosity cement, IM venting, retrograde injection, thorough IM lavage, and intraoperative canal suctioning during cementing all are intended to decrease embolic events and decrease perioperative complications.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Extensive periacetabular bone loss</td>
<td>Rebar augmentation in the form of long, 6.5-mm cancellous screws or Steinmann pins should provide purchase for any posterior column bone and the sacral ala to gain fixation for cementation. Anterior augmentation also may be performed. The construct must be anchored in relatively healthy, noncontiguous bone so that if there is any local progression (such as that which may occur in thyroid and renal cancer) the reconstruction does not fail.</td>
</tr>
<tr>
<td>Instability of proximal femoral replacements</td>
<td>Intraoperatively, the surgeon must carefully determine the appropriate version, which is about 95 to 100 degrees off the midsagittal plane as determined by the linea aspera. Meticulous capsule repair with no. 5, nondissolving polyfilament suture is imperative. Overall length and offset also must be assessed carefully.</td>
</tr>
<tr>
<td>Abductor weakness in calcar- and proximal femoral–replacing reconstructions</td>
<td>Fixation of the residual abductor mechanism must be as rigid as possible. These patients will not be able to protect this reconstruction effectively. I prefer to use two smaller-diameter soft tissue washers to screw down the mechanism. The larger-bore bolts that are available tend to destroy any residual greater trochanter in this compromised patient population.</td>
</tr>
</tbody>
</table>
POSTOPERATIVE CARE
- In this patient population, all reconstruction must permit weight bearing as tolerated, with an assistive device as needed.
- If a drain has been placed for metastatic cases, it should be discontinued within 72 hours.
- Depending on the approach and the extent of the dissection, hip precautions should be implemented for 6 to 12 weeks.

OUTCOMES
- Periacetabular lesions have 70% to 75% satisfactory pain relief and return to at least partial mobility.
- Cemented total or hemiarthroplasty for femoral head, neck, and peritrochanteric lesions remains, in general, the procedure of choice in this patient population, with good to excellent outcomes relative to the omnipresent comorbidities.

COMPLICATIONS
- Periacetabular reconstructions are associated with complication rates of 20% to 30%.
- Cemented femoral arthroplasty is not without inherent risk.
  - Perioperative cardiopulmonary complications associated with cementing hip arthroplasty components are well described.\(^9,11-13\)
  - Cement-associated desaturation and hypotension, pulmonary hypertension, cardiogenic shock, cardiac arrest, and intraoperative death are complications during femoral cementation and component placement secondary to canal pressurization.\(^1,4,7\)
  - Cemented arthroplasty has been shown to be associated with more embolic events than noncemented arthroplasty, with higher IM pressures noted with cementation.\(^9,10\)
  - Any factor that increases extrusion of femoral IM contents has been suggested to elevate the risk of cardiopulmonary embolic complications. In addition to cementation, this includes porous bone and the use of long-stem femoral implants. Long-stem components have been proposed to increase pressurization of the canal, producing more embolic events, with the rate of cardiopulmonary complications reported to be as high as 62%.\(^4,8\)
  - Metastatic bone allows greater extrusion of emboli because of its permeative qualities and increased vascular supply. Thus, patients with MBD undergoing long-stem cemented femoral arthroplasty are at particularly high risk for cardiopulmonary compromise.
- Proximal femoral replacement is associated with complication rates as high as 28%.\(^6\)
- Most experienced surgeons believe that proximal femoral replacement remains the best option for subtrochanteric involvement in proximal femur pathologic fractures secondary to metastatic bone disease.
- No better alternatives with lower risks than proximal femoral replacement exist for this difficult patient population.

REFERENCES
DEFINITION
- Well-fixed femoral and acetabular implants often have to be removed during revision total hip arthroplasty (THA).
- Conditions that necessitate removal of well-fixed implants include:
  - Infection
  - Recurrent dislocations (malpositioned components)
  - Limb-length discrepancy
  - Severe osteolysis
  - Polyethylene wear
  - Locking mechanism failure
  - Failure of other components in the hip such as a femoral stem fracture (FIG 1)
- The key point is to determine which components should be removed and which are well fixed and can be left at the time of revision THA.

ANATOMY
- Important anatomic considerations include the pelvic landmarks and the proximal femoral and diaphyseal anatomy.
- The pelvic landmarks that assist in component removal and positioning include the ischium, pubis, anterior and posterior acetabular columns, anterior inferior iliac spines, transverse acetabular ligament, sciatic notch, and acetabular walls.
- Neurologic structures at risk include the sciatic nerve, which can be identified in three distinct anatomic locations:
  - As it exits the sciatic notch
  - Lying over the ischium posterior and inferior to the posterior acetabular column
  - Beneath the femoral insertion of the gluteus maximus tendon insertion into the posterior femur.
- The superior gluteal nerve is at risk during component removal as it travels anteriorly along the ilium, approximately 4 to 5 cm superior to the tip of the greater trochanter, to innervate the gluteus medius muscle.
- The femoral nerve is well anterior to the hip for most approaches but may be at risk with further anterior dissection and retraction and with anterior supine approaches to the hip.
- The femoral artery and vein are well anterior to the dissection and usually are protected by the iliopsoas tendon and muscle belly.
- The proximal femoral anatomy includes the greater and lesser trochanter and the vastus ridge, which is a point of relatively weak bone in most revisions due to osteolysis, previous trochanteric osteotomies, or previous surgery in this area.
- The femoral diaphyseal anatomy includes the attachments of the vastus musculature at the vastus ridge and posteriorly at the linea aspera.
  - These attachments often must be reflected during extended trochanteric osteotomies to aid in removal of well-fixed femoral implants (FIG 2).

FIG 1 • AP radiograph of a broken T-28 femoral stem. An extended trochanteric osteotomy (ETO) is used for distal well-fixed stem removal.

FIG 2 • Bilateral acetabular component failure with superior displacement on the right hip and medial protrusio on the left. Both are indications for trochanteric osteotomy to facilitate exposure of the acetabulum and possible stem removal.
PATHOGENESIS

- Well-fixed implants may be removed because of polyethyl-
ene wear or in response to osteolysis that occurs as a result of
particulate debris generating an inflammatory (macrophage)
response and subsequent cellular activation with resulting
bone resorption (FIG 3).
- Sepsis around a THA most commonly is caused by a gram-
positive organism and is best eradicated by component re-
moval and two-stage treatment with intravenous antibiotics
and a delay in reimplantation.
  - The sepsis usually progresses rather quickly to the implant
    interfaces despite well-fixed implants and usually cannot be
    treated effectively with irrigation and joint débridement alone.
  - Component removal with attention to bone preservation
    for subsequent reconstruction is crucial.

NATURAL HISTORY

- Retention of well-fixed components has been shown to lead
to acceptable long-term performance on both the acetabular
and femoral side during isolated component revision.2,5

PHYSICAL FINDINGS

- The physical examination of the patient undergoing revision
THA includes:
  - Gait
  - Leg length
  - Distal neurovascular examination
  - Muscle strength about the hip and leg
  - Skin examination and scars over the hip

IMAGING AND OTHER
DIAGNOSTIC STUDIES

- The goal of diagnostic imaging studies is to identify which
implants are well fixed, confirm that there is no infection, and
see what bone stock is available for the revision reconstruction.

- Multiple plain radiographs, CT scanning with possible 3D
reconstruction, scintigraphy (bone scans), and laboratory
screening usually are sufficient.
- Biplanar radiographs of the entire implant and the joint
above and below the prosthesis are essential.
  - These should include the entire cement mantle on ce-
  mented femoral stems.
  - Signs of ingrowth on uncemented stems have been well
described3 (FIG 4A).
- Oblique, or Judet, views of the pelvis can demonstrate the
anterior and posterior columns, because some defects may
not be readily appreciated on routine anteroposterior (AP)
radiographs (FIG 4B).
- In cases that demonstrate significant polyethylene wear or
osteolysis, CT scanning may better demonstrate osteolytic
lesion location and size.
  - These findings are helpful in guiding plans for bone graft-
ing of lytic lesions and identifying remaining bone stock.
  - Plain radiographs usually greatly underestimate the extent
of osteolysis involvement in the pelvis from polyethylene
debris.
- Bone scan examination may demonstrate subtle implant
loosening that may not be appreciated on plain radiographs
or at the time of surgery and may help the surgeon decide
whether to retain or remove implants that appear well
fixed.
- Confirmation of a noninfected arthroplasty is critical prior
to the revision THA.
  - Confirmation is best accomplished by laboratory evalua-
tion, including erythrocyte sedimentation rate (ESR) and
C-reactive protein (CRP). The combination of a normal ESR
and normal CRP has been demonstrated to have a very low
(<1%) likelihood of being infected.6
  - In cases of elevated ESR or CRP, aspiration of the hip is
warranted, with examination of the cell count with differen-
tial and culture of the fluid.
Preoperative Planning

- Appropriate removal instruments and surgical techniques are important considerations as one approaches the revision THA with well-fixed implants.
- When performing revision THA, multiple options for the implant must be on hand to match defects or needs that may be discovered intraoperatively.

Positioning

- In general, patients can be positioned supine or in the lateral decubitus position.
- In the anterior supine approach, the patient is positioned in the supine position and an anterior approach to the hip is performed in the interval between the tensor fascia lata and the sartorius muscles.
- An anterior or anterolateral approach to the hip can be performed in the supine or lateral position and is extensile in both the proximal and distal directions should additional exposure be required.
- The posterior approach to the hip is performed in the lateral decubitus position.
- At our institution, we use a pegboard positioner.
- An axillary roll is used to provide protection for the brachial plexus during surgery.

**TECHNIQUES**

**APPROACH**

**Anterior Supine**

- The patient is positioned in the supine position and an anterior approach to the hip is performed in the interval between the tensor fascia lata and the sartorius muscles (TECH FIG 1A,B).
- This technique is suitable for polyethylene exchange alone, in which the femoral component is well fixed and there is no significant need for bone grafting in the posterior aspect of the acetabulum (see Fig 3).
- Bone grafting is possible through the holes in the acetabular component or through a small “trap-door” above the acetabulum (TECH FIG 1C).
- This approach retains much of the posterior capsule and structures, which likely reduces the incidence of dislocation after revision.
- The femoral head is retracted posteriorly (TECH FIG 1D), and a new liner is inserted (TECH FIG 1E).

**Lateral**

- A direct lateral approach to the hip involves a split in the anterior third of the gluteus medius and minimus musculature.4
The length of the osteotomy is determined by the amount of prosthesis that is well fixed or the distal extent of the cement column that needs to be removed. Approximately a third of the lateral portion of the femoral circumference is part of the osteotomy (TECH FIG 2A).

The vastus lateralis remains attached to the lateral portion of the osteotomy but is reflected anteriorly to allow visualization of the lateral and posterior femoral cortex.

An oscillating saw is used to perform the posterior portion of the osteotomy just superior to the linea aspera. The gluteus medius remains attached.

The distal extent of the osteotomy is beveled in the distal and anteroposterior direction. Alternatively, the osteotomy can be performed with a high-speed burr with a thin tip (TECH FIG 2B).

The anterior portion of the osteotomy is made with a small (¼-inch) osteotome perforated through the vastus musculature. Multiple perforations are made in the same plane to create the osteotomy.

The capsule surrounding the prosthesis below the greater trochanter is released or excised and the “shoulder” of the prosthesis exposed.

The entire extended trochanteric fragment is reflected anteriorly with care not to fracture the tip of the trochanteric fragment, because this is the weakest point in the osteotomized fragment (TECH FIG 2C).

**EXTENDED TROCHANTERIC OSTEOTOMY**

- The length of the osteotomy is determined by the amount of prosthesis that is well fixed or the distal extent of the cement column that needs to be removed. Approximately a third of the lateral portion of the femoral circumference is part of the osteotomy (TECH FIG 2A).
- The vastus lateralis remains attached to the lateral portion of the osteotomy but is reflected anteriorly to allow visualization of the lateral and posterior femoral cortex.
- An oscillating saw is used to perform the posterior portion of the osteotomy just superior to the linea aspera. The gluteus medius remains attached.
- The distal extent of the osteotomy is beveled in the distal and anteroposterior direction. Alternatively, the osteotomy can be performed with a high-speed burr with a thin tip (TECH FIG 2B).
- The anterior portion of the osteotomy is made with a small (¼-inch) osteotome perforated through the vastus musculature. Multiple perforations are made in the same plane to create the osteotomy.
- The capsule surrounding the prosthesis below the greater trochanter is released or excised and the “shoulder” of the prosthesis exposed.
- The entire extended trochanteric fragment is reflected anteriorly with care not to fracture the tip of the trochanteric fragment, because this is the weakest point in the osteotomized fragment (TECH FIG 2C).
Curved Bennett-type retractors are inserted distal to the osteotomy for soft tissue retraction and the Charnley-type hip retractor anterior arm is carefully secured to the trochanteric fragment anteriorly to expose the femoral prosthesis (TECH FIG 2D).

Anterior and medial capsular attachments are taken down to the level of the psoas tendon. All tissue lateral to the psoas tendon can be removed at this point if needed to allow visualization of the stem.

Osteotomes, ultrasonic devices, or high-speed burrs now have access to the cement–implant and cement–bone interfaces or the ingrowth interface, as needed for removal.

The femoral preparation for long-stem implant insertion is completed with flexible reamers and proximal femoral tapered reamers.

The trial implants are inserted and a trial reduction performed before the trochanteric fragment is reattached. The osteotomy is reduced and secured with looped Luque wires (TECH FIG 2E).

ACETABULAR REMOVAL

The goal in acetabular removal is to preserve as much of the remaining bone as possible. It is important not to gouge the acetabulum or to break off large pieces by aggressively twisting or pulling a well-secured cup.

Acetabular osteotome systems facilitate cup removal by using the center of the acetabular polyethylene as a reference for osteotome insertion. Osteotomes match the radius of curvature of the cup. The center of rotation of the acetabular component allows thin osteotome insertion precisely in the bone implant interface (TECH FIG 3A).

The osteotome blade is inserted and turned in a firm, controlled manner, maintaining its orientation to the rim of the cup.

First, a small osteotome is inserted that matches the radius of the acetabular component. It is used to enter the bone–implant interface only around the rim of the ingrown acetabular component (TECH FIG 3B,C).

Successively longer acetabular osteotomes are then used around the entire rim of the component to divide more medial ingrown interfaces (TECH FIG 3D).

A handle permits the acetabular explant chisel to be rotated around the circumference of the component to further loosen the implant and remove the cup with minimal bone loss (TECH FIG 3E).
**TECH FIG 3**  •  **A.** The acetabular osteotome used to remove cups allows thin osteotome insertion precisely in the bone implant interface. **B.** A small osteotome is first used to enter the bone–implant interface around the rim of the acetabular component. **C.** Osteotome shown with the implant removed. **D.** A longer acetabular osteotome removes the medial ingrown interfaces. **E.** Using the acetabular explant chisel on a handle, the implant is removed with minimal bone loss. (Courtesy of Zimmer, Inc., Warsaw, IN.)

### PEARLS AND PITFALLS

<table>
<thead>
<tr>
<th>Acetabular deficiencies</th>
<th>▪ Osteolysis and bone loss behind well-fixed acetabular components is underestimated on plain radiographs. A simple polyethylene exchange may become a much more extensive revision if proper preoperative evaluation such as CT scanning has not been completed.</th>
</tr>
</thead>
</table>
| Extended trochanteric osteotomy | ▪ Bevel the distal transverse arm of the osteotomy to prevent distal fracture propagation.  
▪ Pass a cerclage wire distal to the osteotomy before femoral preparation and trial and final implant insertion.  
▪ Pay careful attention to trochanteric osteolysis and fracture risk at the vastus ridge at the junction of the vastus lateralis and the abductor attachment into the trochanter.  
▪ Have adequate bone graft available, including morselized cancellous graft and cortical struts for contained and uncontained defects.  
▪ With distally fixed stems combined with an ETO, a tight distal diaphyseal fit must be obtained, achieving three-point fixation.  
▪ Postoperative radiographs are needed, because the intraoperative fracture rates are higher for revision THA and ETO cases.  
▪ An ETO can be combined with a proximal reduction or angular osteotomy.  
▪ Leave vastus muscle attached to the trochanteric fragment to provide adequate blood supply for osseous healing and implant stability. |
Acetabular removal

- Thin osteotomes based on the cup and head size reduce bone loss during removal of well-fixed acetabular components.
- The polyethylene should be removed from the acetabular component to allow screw removal, then replaced for a guide or reference for removal instruments.
- Cementing an acetabular polyethylene shell is an option if the locking mechanism is not functional after polyethylene component removal.

POSTOPERATIVE CARE

- Weight bearing is restricted to about 50% for 6 to 8 weeks if an implant has been reinserted and bone graft has been used.
- With polyethylene exchanges and component retention of osseointegrated implants, weight bearing as tolerated is recommended.
- When an implant is removed and an antibiotic-impregnated static spacer is inserted, foot-flat (essentially non-weight bearing) weight bearing is recommended. We combine this with a hinged knee brace locked in extension, which allows wound care but limits motion and provides additional support while allowing mobilization during the time of IV antibiotic therapy.

COMPLICATIONS

- Femoral fractures are common about the trochanteric region and in the diaphysis during removal of well-fixed femoral implants.
- Isolated component revision has a higher dislocation rate than primary revision THA.
- Acetabular deficiencies may be extensive in the face of polyethylene wear and osteolysis.

OUTCOMES

- Aribindi et al\textsuperscript{1} reported on the outcomes associated with THA revision with an extended trochanteric osteotomy in 122 cases with a minimum of 1 year of follow-up (average, 2.6 years).
  - No non-unions, no migration greater than 2 mm
  - All healed by 3 months
  - 92% bone ingrowth, one stem revised for loosening
  - Dislocation rate 10% (three required revision)
  - 20% intraoperative fracture rate

REFERENCES

DEFINITION
- A fluted stem can be used to revise a loose femoral implant with one or more of the following:
  - Cavitary or segmental defects
  - Femoral malalignment
  - Periprosthetic fracture
  - Stress-shielded or sclerotic bone secondary to prior fracture fixation

ANATOMY
- The anatomic structures most relevant to revision arthroplasty in patients with femoral bone loss are the proximal aspect of the femur and the femoral shaft, as well as the surrounding soft tissues.
- The proximal aspect of the femur is composed of the head, the neck, and the greater and lesser trochanters.
- Important soft tissues include the iliotibial band and the tensor fascia lata, the gluteal muscles, the short external rotators and the joint capsule, the iliopsoas, and the quadriceps musculature (FIG 1A).
- Vascular and neurologic structures include the femoral artery and vein and the sciatic nerve.
- The AAOS classification is used to describe femoral bone loss5 (Table 1; FIG 1B).

PATHOGENESIS
- Normal wear of the acetabular liner produces particulate polyethylene debris. The presence of this debris increases over time, leading to a macrophage response that results in periprosthetic bone loss. Aseptic loosening may occur secondary to this particle-induced periprosthetic osteolysis.
- This mode of failure is the primary reason for revision hip arthroplasty.

NATURAL HISTORY
- The implant loosens as a result of progressive bone loss.
- The loose implant leads to further bone loss.
- Cortical thinning frequently occurs.
- Angular deformation (often varus) results.
- Progressive cortical thinning may result in fracture.

PATIENT HISTORY AND PHYSICAL FINDINGS
- Patient history should involve an in-depth conversation related to the location and type of pain that the patient is experiencing (Table 2).
- A complete medical and surgical history is necessary to document all information pertaining to the index procedure, including the initial diagnosis, date of surgery, complete operative notes with detailed descriptions of the components used, and the dates of any postoperative complication.
- Other systemic medical conditions and recent surgical or medical treatments should also be documented to ensure that the patient can tolerate and will benefit from hip revision.
- The physical examination should include the following:
  - Gait evaluation. Painful total hip arthroplasty (THA) may result in shortened stance phase or stride length, or abnormal pelvic rotation. A Trendelenburg gait or abductor lurch may raise concern regarding hip abductor function that can limit success of revision.
  - Trendelenburg test is considered positive if pelvis on the nonstance side moves into a position of relative adduction; this may indicate abductor weakness or trochanteric nonunion.
  - Range of motion should be pain-free throughout range. Pain suggests mechanical dysfunction. A palpable or audible click or clunk may indicate head subluxation or a loose component.
  - Hip abductor strength may indicate abductor weakness, trochanteric bursitis, abductor avulsion, trochanter fracture, or a loose femoral component.
  - A slight difference of less than 1 cm in true leg length is considered normal, though it may cause symptoms in some patients. Progressive leg-length discrepancy suggests implant subsidence.
  - Apparent leg length may be affected by atrophy, obesity, or asymmetric positioning of the legs. Values may indicate abductor or adductor contractures, or pelvic obliquity due to scoliosis.
  - Evaluate the skin around the hip to gauge the risk for infection and to assess its ability to heal postoperatively.
  - A careful neurologic and vascular evaluation should be performed to rule out extrinsic etiology for hip or thigh discomfort. It will also serve as a baseline for the postoperative exam.

Bone
- Careful evaluation of the preoperative radiographs is imperative to identify bony deficiencies. The greater trochanter is commonly sclerotic and fragile and is easy to fracture. Nonunion can result despite rigid fixation of intraoperative fractures. Hardware over the trochanter can result in a painful bursitis.
- Proximal bone deficiencies around the lesser trochanter can be so profound that a fluted stem is not suitable for femoral revision and a fully porous coated stem for diaphyseal fixation is preferable.
- Diaphyseal defects in the femur are important to identify since it is critical for the stem to bypass cortical deficiencies by at least two cortical diameters.

Soft Tissue
- The hip abductors require careful preoperative evaluation and intraoperative inspection since they are critical to postoperative hip stability and gait. Prior hip surgery may result in a weakened gluteus medius.
The gluteal sling refers to the insertion of the gluteus maximus on the posterolateral border of the proximal femoral shaft. The 5-cm insertion frequently needs to be partially or completely released to gain exposure or correct leg length. It should be repaired to a tendon stump at the end of the surgery.

The vastus lateralis may be elevated from its posterior border to give the surgeon access to the femoral shaft for correction of bony deformity, fracture repair, and cable placement.

Neurovascular Structures
- The sciatic nerve is frequently encased in scar during revision hip surgery. It is located 1 to 2 cm posterior to the posterior hip joint capsule and the short external rotators are often scarred together. They need to be tagged and preserved for later repair if a posterior approach to the hip has been used. Many times, the anterior joint capsule is scarred and must be completely resected to correct offset and leg-length abnormalities.
- Polyethylene debris may be located in the iliopsoas sheath and should be eliminated during the hip revision. The iliopsoas may require anterior release to correct leg length and preoperative flexion contractures.

### Table 1
**AAOS Classification of Femoral Bone Loss**

<table>
<thead>
<tr>
<th>Classification</th>

Step-by-Step Procedure for Templating Prior to Revision Hip Arthroplasty With a modular, fluted stem.

<table>
<thead>
<tr>
<th>Step</th>
<th>Primary Objective</th>
<th>Instructions</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>Mark and measure leg lengths</td>
<td>Compare location of the lesser trochanter of the operative and nonoperative leg in relation to either the transischial or transobturator lines. Be sure to measure with a magnified ruler.</td>
</tr>
<tr>
<td>2</td>
<td>Identify acetabular landmarks</td>
<td>Assess position of the teardrop, superolateral lip, and the medial wall (Kohler’s line).</td>
</tr>
<tr>
<td>3</td>
<td>Template acetabulum</td>
<td>Assess bony anomalies and decide what acetabular reconstruction is most reliable. Position the hemisphere to contact the appropriate landmarks with the proper abduction, medializing as needed without passing Kohler’s line.</td>
</tr>
<tr>
<td>4</td>
<td>Determine center of rotation</td>
<td>Lateralized acetabular implants can be used to compensate for medial bone loss. Mark center of rotation.</td>
</tr>
<tr>
<td>5</td>
<td>Draw lateral femoral line</td>
<td>Draw straight line up the endosteum of lateral femoral cortex, which represents the final lateral position of the implant. Failing to respect or address this line can lead to lateral perforation or varus implantation.</td>
</tr>
<tr>
<td>6</td>
<td>Select stem diameter</td>
<td>With magnified ruler, measure narrowest isthmic endosteal diameter. This measurement determines the diameter of the prosthesis. For example, if the canal diameter is 17 mm, then a 22 × 17 stem would be selected.</td>
</tr>
<tr>
<td>7</td>
<td>Select stem length</td>
<td>Four lengths available: standard, long, extra-long, and extra-extra-long. Review the entire femoral length, and attempt to bypass the lowest femoral defect by 2.5 to 3 canal diameters. Also, attempt to bypass level of previous stem or cement plug.</td>
</tr>
<tr>
<td>8</td>
<td>Position stem and select neck</td>
<td>Judge center of rotation for stem/neck/head combination to obtain appropriate length. Consider calcar-replacing stems and be careful if losing offset.</td>
</tr>
<tr>
<td>9</td>
<td>Determine level of sleeve</td>
<td>Mark proximal level of sleeve as indicated on the template. Make certain to mark both the AP and lateral radiograph at the desired level, which may be difficult with the lateral film.</td>
</tr>
<tr>
<td>10</td>
<td>Select sleeve size</td>
<td>Use anteroposterior and lateral views for sleeve sizing. Overlay sleeve template for best anteroposterior fill at the correct level. Position the sleeve on the anteroposterior view, and choose position and size of triangle.</td>
</tr>
<tr>
<td>11</td>
<td>Select neck length</td>
<td>Mark neck length for the +0 head so less likely to need a skirt.</td>
</tr>
<tr>
<td>12</td>
<td>Final review</td>
<td>Recheck leg lengths and verify neck style and length.</td>
</tr>
</tbody>
</table>
Most fluted stems have a proximal sleeve of varying length that allows for optimal fit and fill of the proximal femur. The flutes increase distal fill and increase resistance to rotational stress.

Preoperative Planning

- Template using recent preoperative anteroposterior (AP) and lateral radiographs (Table 3). AP and lateral radiographs of the femoral shaft are required if long, extra-long, or extra-extra-long stems are going to be used.
- A pathologist must be available to look at the frozen section.
- Materials needed include previous surgery notes, possible polyethylene liner exchange options, revision acetabular components (even if the socket looks stable), fully porous coated femoral component if proximal fixation is insufficient for use of a fluted stem, particulate and structural allografts, and cables.

Positioning

- Following application of general anesthesia and insertion of a Foley catheter, the patient should be positioned on a pegboard in the lateral decubitus position with bony prominences padded.
- Perfect positional stability of the patient’s pelvis is ensured before preparation and draping.
- Wide skin preparation is performed, with access to the distal femur.

Approach

- Posterolateral/posterior approach
- Anterolateral/Harding approach

### ROUTINE REVISION WITHOUT DIAPHYSEAL DEFECT

#### Site Preparation

- Use trochanteric osteotomy/slide if needed for exposure or for cement/implant removal.
- Avoid extended trochanteric osteotomy, since this will compromise proximal fixation.
- Carefully assess the proximal femur above the lesser trochanter.
- Perform straight reaming of the proximal diaphysis until cortical chatter is achieved. Reaming should be done to a depth determined by comparing a line on the reamer to the tip of the trochanter1 (TECH FIG 1A).
  - The diameter of the last reamer will determine the size of the implant and reflects the diameter of the distal end of the implant.
- Prepare the metaphysis with the conical reamers that correspond with the last straight reamer. Cone reaming should stop whenever contact with structurally sound cortical bone is obtained. A small cortical edge should be palpable at the inferior end of the conically reamed bone.
  - Take care to insert the conical reamer to the level that corresponds to the preoperatively templated level of the upper portion of the sleeve.
- If using the S-ROM system, use the calcar miller to prepare the femur for the triangular modular sleeve (TECH FIG 1B).

#### Implant Placement

- Perform trial reduction after placing the trial sleeve and femoral stem to assess version, range of motion, and laxity. The modular system allows complete freedom to vary antversion regardless of proximal femoral geometry (TECH FIG 2A–D).
- Insert sleeve, and then finish by inserting femoral stem (TECH FIG 2E).

**TECH FIG 1**  •  A. Straight reaming of the femur is carried out until contact with diaphysis is obtained. B. Calcar miller that is used for preparation of proximal femur as part of this prosthesis.
**ROUTINE REVISION WITH DIAPHYSEAL DEFECT**

- Plan to bypass the diaphyseal defect by two cortical widths with a long, extra-long, or extra-extra-long bowed stem.
- Pass a long guidewire to ensure that there are no holes in the cortical bone.
- Flexibly ream until good cortical chatter is achieved in the diaphysis. You must flexibly ream to 1.5 mm greater than the minor diameter of the shaft of the implant (e.g., ream to 14.5 mm for an 18 ¥ 13 stem) when using a long, extra-long, or extra-extra-long stem.
- Straight ream proximally to the same diameter as the minor diameter of the implant.
- Conical and miller reaming is performed in the manner described in the previous section.
- Place trial implants.
- When inserting the true implants, do not completely seat the proximal sleeve prior to placing the stem when using a long, extra-long, or extra-extra-long sleeve. The sleeve should be inserted to within 1 to 2 mm of the intended location. The stem should then be inserted through the sleeve and it should engage the sleeve as they are finally seated together.
- The bowed implant has 15 degrees of anteversion built into it. The surgeon can actually place up to 25 to 30 degrees of anteversion on the femoral stem if necessary.
- Struts are usually not needed, though they can be used to improve bone stock.

**EXTENDED TROCHANTERIC OSTEOTOMY NEEDED OR DIAPHYSEAL OSTEOTOMY OR OPEN REDUCTION AND INTERNAL FIXATION OF A PERIPROSTHETIC FRACTURE DISTAL TO A LOOSE STEM**

- Remove stem and cement if necessary through the top of the femur or through the fracture site if present.
- Perform exposure posterior to the vastus lateralis to expose the femoral shaft.
- Perform the osteotomy or expose the fracture and place a cable around the distal diaphyseal fragment.
- Straight ream or flexibly ream the distal diaphyseal fragment until cortical chatter is noted. The size of the last reamer will dictate the size of the implant.
- Use bone clamps to gain control of the proximal segment and then straight ream to the diameter of the last reamer used on the distal fragment. Conical reaming and proximal milling should be performed as described earlier. It may be advisable to place a cable at the level of the sleeve at this point to prevent fracture.
- Reduce the proximal fragment to the distal fragment with bone clamps if needed.
- Place the trial implant crossing the fracture or osteotomy with the stem.
- Reduce the hip and assess leg lengths, offset, and soft tissue tension. Rotational stability will not be obtained at the fracture or osteotomy site at this time, so a true stability examination is not possible.
- Place cables around structural allograft and begin to tighten if allograft struts are needed.
TECH FIG 3 • Preoperative and postoperative AP radiographs of a patient with severe proximal deformity that necessitated a cortical osteotomy for insertion of the prosthesis and femoral realignment.

USE OF A FLUTED STEM WITH A PROXIMAL FEMORAL ALLOGRAFT

- Choose a large proximal femoral allograft (critical).
- Expose the femoral diaphysis by proceeding posterior to the vastus lateralis.
- Decide on the level of the graft–host junction and divide the femur at that level. A step cut is not necessary because of the rotational stability of the bowed, slotted stem.
- Ream the distal diaphysis line to line with a straight or flexible reamer until cortical chatter is achieved. The last reamer determines the size of the implant.
- Place the allograft in a bone vise and prepare the allograft with a flat neck cut followed by straight reaming to 1 to 2 mm larger than the distal diaphysis diameter. Conical reaming and proximal milling then occur on the proximal femoral allograft as previously described.
- Make a provisional distal cut on the allograft, leaving it 1 cm long.
- Make a longitudinal cut on the proximal native femur to open it up so the allograft can be inserted within it. Do not remove any soft tissue attachments from the native proximal femur.
- Perform a trial reduction by placing the trial within the allograft and inserting the distal portion of the stem into the native femoral diaphysis. Attempt to reduce the hip and assess leg lengths. Remove bone from the distal tip of the allograft to equalize leg lengths. Make sure there is good bone contact at the allograft–host bone junction. Also, remove bone from the allograft greater trochanter to allow the native trochanter to be placed in an anatomic position overlying the allograft.
- Remove the allograft and stem and roughen the exterior minimally in the areas where the allograft will have contact with host bone.
- Remove the stem from the allograft and pulse lavage and dry the interior of the allograft. Pass two cables through the lesser trochanter; these will later be used with a claw to fasten the native greater trochanter.
- Downsize the sleeve to allow for a cement mantle and assemble the stem and sleeve on the back table.
- Cement the fluted stem and sleeve into the allograft, making sure that all of the cement is wiped off the distal portion of the stem. Keep cement off the distal portion of the allograft to allow complete contact with the host distal femur.
- After cement hardening, insert the allograft–stem composite into the native femur. It is rarely necessary to ream the distal femur an additional 0.5 mm to prevent fracture. Rotational stability at the graft–host junction should be complete at this time (TECH FIG 4A).
- Use native bone at the graft–host junction to serve as struts. A claw is typically placed on the native trochanter to help fasten the native greater trochanter to the allograft (TECH FIG 4B).
- The remainder of the native proximal bone is attached to the allograft with the soft tissue attachments maintained.
- Remove trial and place implant. If the implant will not fit in the distal fragment, it may be necessary to ream up 0.5 mm to avoid fracture (TECH FIG 3).
- Tighten cables.
- Inspect for iatrogenic fracture.
- Consider additional bulk allograft.
- Perform a gentle stability examination.
- Perform routine closure using posterior capsular repair.
- Administer antibiotics for 3 days or until cultures are negative.
- Brace for 6 to 12 weeks.
- Leg lengths are assessed by soft tissue tension, preoperative templating, and comparison with down leg.
PEARLS AND PITFALLS

Avoid trochanteric osteotomy and extended trochanteric osteotomy (ETO) if possible. Patients get well quickly if osteotomy can be avoided and the risk of sleeve subsidence reduced.

Ensure complete cement removal. If cement is not completely removed, reamers will take away bone since it is often less hard and cause perforations.

Confirm no perforations have occurred. Use long guidewire down diaphysis or fluoroscopy if needed.

If perforation occurs, expose perforation and treat fracture appropriately. Bypass with stem, strut graft, etc.

If using a long stem, consider AP and lateral radiography of distal femur prior to leaving OR.

Do not be afraid to use larger heads in older patients. Reduce dislocation risk.

POSTOPERATIVE CARE

- Weight bearing as tolerated in simple cases with standard, straight stems
- Knee immobilizer while sleeping to help prevent dislocation
- Touchdown weight bearing and bracing for 6 to 12 weeks in complex cases with osteoporosis or if fracture or osteotomy healing is needed
- Pharmaceutical and mechanical deep vein thrombosis prophylaxis
- Follow cultures.

OUTCOMES

- When used for proximal femoral bone loss or other complex revisions, previous authors have reported excellent radiographic and clinical outcomes with the S-ROM system, including no evidence of osteolysis, mean postoperative Harris hip score of 82, and 84% patient satisfaction.3,4
- The S-ROM system has been reported to have a 5-year survival rate of 96%, with a 5% rate of mechanical failure.9,11
- Inferior outcomes have been associated with the use of large stem diameters.
One study attributed persistent thigh pain to the use of stems greater than 17 mm in diameter.\(^3\)

A second study reported a significantly increased incidence of stress shielding, as well as a lack of bony ingrowth, with stem diameters greater than 16 mm.\(^11\)

**COMPlications**

- Aseptic loosening
- Infection
- Dislocation
- Leg-length discrepancy
- Fracture or osteotomy nonunion
- Trochanteric fracture

**References**

DEFINITION
- Proximal femur replacement is a salvage limb-sparing surgery for nononcologic and oncologic indications that in the past were treated with a major amputation.
- During the past decade remarkable advances in the field of revision hip reconstruction have been made. One such improvement has been the introduction of second-generation modular prosthetic components (FIG 1), which provide improved ability to restore limb length and achieve optimal soft tissue tension, both of which may reduce the incidence of instability that often followed insertion of a monolithic megaprosthesis. A new generation of megaprostheses also provides a better environment for soft tissue reattachment and the ability to reapproximate the retained host bone to the prosthesis.

ANATOMY
- The abductors are the gluteus medius and minimus muscles, the tensor fascia lata muscles, and the iliotibial band. The adductors are the adductor brevis, adductor longus, and gracilis muscles, and the anterior part of the adductor magnus muscle. The external rotators are the piriformis, quadratus femoris, superior gemellus, inferior gemellus, obturator internus, and obturator externus muscles.
- Abductors are important stabilizers of the hip that are innervated mainly by the superior gluteal nerve. The nerve exits the pelvis via the suprapiriform portion of the sciatic foramen along with the superior gluteal vessels. Palsy results in abductor lurch, a Trendelenburg gait.

PATHOGENESIS
- Femoral bone loss is a constantly rising, predominantly complex and challenging problem in revision arthroplasty.
- Numerous factors may contribute to the loss of femoral bone stock encountered in revision hip arthroplasty:
  - Osteolysis secondary to particle debris
  - Stress-shielding with adaptive bone-remodeling
  - Previous infection
- Natural processes of aging
- Periprosthetic fracture
- Multiple previous failed reconstructive procedures with insertion and removal of implants also compromise the integrity of the bone stock and adversely affect the integrity and function of the abductor muscles.
- Options available for dealing with severe femoral bone loss include the use of a long cemented stem or press-fit stems, impaction allografting, resection arthroplasty, allograft prosthetic replacement, and modular replacement.
- An allograft–prosthesis composite potentially increases bone stock in the proximal part of the femur and provides sites for soft tissue attachment, including the abductor muscles. The use of an allograft–prosthesis composite is limited due to the risks of infection, junctional nonunion, dislocation, and aseptic loosening.
- A proximal femoral replacement probably is more available to most surgeons than a proximal femoral allograft, and it is less technically demanding to implant.
- Zehr et al28 conducted a comparative study in which the use of an allograft–prosthesis composite was found to be marginally better than proximal femoral replacement for reconstruction after tumor resection.

NATURAL HISTORY
- The megaprosthesis is valuable in the armamentarium of the reconstructive hip surgeon who treats patients with extensive bone loss for whom other available reconstructive procedures cannot be utilized.
- This prosthesis will have an unacceptably high failure rate in younger patients, and other reconstructive options should be explored.

PATIENT HISTORY AND PHYSICAL FINDINGS
- Assessment of the present and past medical history, physical examination results, and radiographic findings lead to a correct diagnosis of hip pathology in most patients.
- Intra-articular or acetabular pathology usually presents as groin pain.
- Thigh pain (especially start-up pain) is more indicative of a loose femoral stem.
- Patients may present with severe knee pain as a result of hip pathology. Any patient with knee pain should be evaluated for hip pathology.
- Neurovascular examination and examination of the spine and abdomen should be conducted to exclude other reasons
of hip pain, such as neuropathies, vascular claudication, and spinal stenosis.

- Specific tests for the hip with evaluation of range of motion and leg lengths should be documented.
  - Leg-length assessment for apparent or functional leg length discrepancy; a deficiency may be due to pelvic obliquity, contractures, or scoliosis.
  - Trendelenburg test: inability to stabilize the pelvis indicates abductor weakness.
  - Straight leg raise: radicular pain may be felt along the leg.
  - Thomas test: evaluates for hip flexion contracture.
  - Stinchfield test: groin pain or weakness may indicate intra-articular hip pathology.

- Initial history taking should begin with a discussion of the patient’s chief complaint. The location and nature of the patient’s pain can guide the surgeon to the proper diagnosis.
- A thorough review of the patient’s medical history along with a complete review of systems will help the surgeon to identify any potential factors that may lead to perioperative complications and provides an opportunity to medically treat or optimize the patient before the planned operation.
- Sources of potential or concurrent infection must be discovered, and proper evaluation and treatment should be performed well in advance of the surgical procedure.
- Negative hip aspirations do not completely rule out infection and should be followed up with intraoperative tissue sampling with frozen sections after alerting the appropriate pathology department personnel well before the planned surgical date.
- Patients with any history of chronic venous stasis ulcers, previous vascular bypass surgery, or absent distal pulses should be evaluated by a vascular surgeon.
- The physical examination should begin with the analysis of the patient’s gait. Use of ambulatory assistive devices, a limp, or a deformity of the lower extremity should be noted.
- The antalgic gait is a result of pain in all phases of ambulation with weight bearing and is characterized by a shortened stance phase indicating hip-joint disease.
- The Trendelenburg gait or abductor lurch indicates either paralysis or loss of continuity of the abductor musculature and is identified by observing the shift of the patient’s center of gravity over the affected extremity during the stance phase of gait.
- Inspection of previous surgical wounds should be routinely performed. Planning of the surgical incision is important in determining the approach for the surgical reconstruction, and, although skin flap necrosis after hip surgery is rare, the maximum distance and angles used should be optimal to avoid this complication.
- The active and passive ranges of motion of the hip should be identified along with the strength of the hip girdle musculature.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Proximal and total femur resections are major surgical procedures that necessitate a detailed preoperative evaluation.
- Physical examination and imaging studies aid in determination of the extent of bone resection and dimensions of the required prosthesis; the extent of soft tissue resection and reconstruction possibilities; and the proximity of the scarred-in femoral vessels, femoral nerve, and sciatic nerve.
- Most complications can be avoided by anticipating them before surgery and modifying the surgical technique accordingly.
- Plain radiographs are used to evaluate the extent and level of bone destruction. If needed, CT scanning can be added for further delineation of the femur and acetabulum bone structure.
- MRI is used to evaluate the medullary canal and soft tissue around the hip joint.
- Three-phase bone scan is essential to determine the presence of metastatic bone disease.
- Angiography of the iliofemoral vessels is essential before proximal femoral replacement if distortion of the anatomy following multiple previous surgeries is suspected.

**DIFFERENTIAL DIAGNOSIS**

- Osteomyelitis
- Metastatic lesions
- Primary bone tumors, eg, multiple myeloma, chondrosarcoma
- Periprosthetic fracture
- Osteolysis
- Aseptic loosening
- Paget disease
- Metabolic disease

**NONOPERATIVE MANAGEMENT**

- For the indications discussed in this chapter, the only reasonable option would be a surgical one. If the patient’s medical problems are serious enough to put off the surgery, however, an antidislocation brace with protected weight bearing can be used.

**SURGICAL MANAGEMENT**

- Use of the megaprostheses (ie, proximal femoral replacement and total femur replacement) is reserved to expedite recovery for elderly or sedentary patients with massive bone loss that may have occurred after failed total hip arthroplasty (FIG 2A,B), deep infection, periprosthetic fracture (FIG 2C,D), fracture nonunion with failed multiple attempts at osteosynthesis, and hip salvage after a failed resection arthroplasty.
- In younger patients with bone loss of high magnitude that cannot be reconstructed by conventional means, an allograft prosthetic composite is preferred over femoral prosthetic replacement.
- An important prerequisite for the use of prosthetic femoral replacement and allograft prosthetic composite is the availability of sufficient distal femoral length (less than 10 cm) for secure fixation of the cemented or uncemented femoral stem.
- When distal bone is severely deficient, total femoral replacement may be considered.
- The presence of superficial or deep infection around the hip is an absolute contraindication.
- Additional contraindications include lack of cooperation on the part of the patient, vascular insufficiency that may prevent healing, and the presence of significant medical comorbidities precluding administration of anesthesia.

**Preoperative Planning**

- The importance of preoperative planning in hip arthroplasty in general, and in proximal femur reconstruction in particular, cannot be overstated. These cases can be technically demanding, requiring meticulous attention to detail to achieve success.
■ Proximal femur reconstruction is performed for metaphyseal–diaphyseal lesions that extend below the lesser trochanter, cause extensive cortical destruction, and spare at least 3 cm of the distal femoral diaphysis.
■ Total femur resection is performed for diaphyseal lesions that extend proximally to the lesser trochanter and distally to the distal diaphyseal–metaphyseal junction and cause extensive bone destruction.
■ Preoperative clinical and radiographic (standing films) assessment of limb length are carried out and recorded.
■ Intraoperative monitoring of the sciatic and femoral nerves may be required in patients in whom extensive limb lengthening (more than 4 cm) is anticipated.
■ Preoperative templating to select the appropriate stem length and diameter is essential.
■ Problems with removal of existing hardware, specific needs for acetabular reconstruction, the potential need for insertion of constrained liners, and determining the absence of previous infection should be anticipated and addressed appropriately.
■ Even with the most accurate preoperative measurements, a variety of prosthesis sizes should be available in the operating room, because intraoperative adjustments with change in the anticipated size of the prosthesis are common.
■ The representative of the company that manufactured the prosthesis to be used in the proximal femur reconstruction should be present in the operating room.
■ The operating room personnel, particularly the scrub person, who assist with this procedure should be experienced. An experienced anesthesia team should administer anesthesia, because these patients often are elderly and frail, and invasive monitoring often is warranted.
■ Regional anesthesia is preferred. Intraoperative blood salvage (ie, with a cell saver) should be used in these patients.
■ The anesthesia team should be prepared for the possibility of large volume loss and encouraged to monitor this closely.
■ Invasive monitoring with arterial lines or pulmonary catheters may be necessary in some patients.

Positioning
■ We place the patient in the lateral decubitus or supine position.
■ Nonpermeable U-drapes are used to isolate the groin.
■ The distal third of the extremity also is isolated from the field using impermeable drapes. The knee must be included in the operative field, even in patients undergoing proximal femoral replacement.
■ Extension of the incision and arthrotomy of the knee to address intraoperative problems such as fractures extending distally is not uncommon.
■ The skin is scrubbed with povidone-iodine solution for at least 10 minutes and DuraPrep (3M, St. Paul, MN) applied before application of Ioban (3M) to the skin.

Approach
■ We use the direct lateral approach (Hardinge approach) or the posterolateral approach with trochanteric slide osteotomy to gain access to the hip and maintain a low threshold to extend the incision as needed (FIG 3).

FIG 2 • A. AP radiograph of a patient with multiple previous surgeries for deep infection that had resulted in massive proximal femoral bone loss. B. A megaprosthesis was used for reconstruction. C. A 72-year-old patient presenting with periprosthetic fracture. D. Because of severe bone loss, reconstruction with megaprosthesis was carried out.

FIG 3 • Diagram showing the placement of incision.
EXPOSURE

- When extensile exposure of the femur is needed, a vastus slide osteotomy, as described by Head et al.,\(^1\) mobilizes the anterior abductor, vastus lateralis, and vastus intermedius muscles anteriorly in unison and exposes the anterior and lateral aspects of the femur (TECH FIG 1).
- Meticulous soft tissue handling helps the tissues to heal and minimizes postoperative complications.
- Deep tissue specimens for frozen section and culture are obtained in all cases. Meticulous débridement of the hip is carried out to remove previous metal debris and hardware around the femur, if present.
- When a posterolateral incision is routinely used for proximal femur resections, the incision can be extended to the anterolateral aspect of the patellar tendon if a total femur resection is required.
- The abductors are identified, as are their anterior and posterior intervals. The abductors are transected through their tendinous attachments and retracted, exposing the hip joint and acetabulum.
- The vastus lateralis is reflected distally from its origin, and the posterior perforating vessels are ligated. The vastus lateralis has to be preserved because of its future role in soft tissue coverage of the prosthesis; it will be advanced proximally and sutured to the abductors.
- Care is taken not to ligate its main pedicle, which crosses anteriorly and obliquely along the rectus femoris fascia.

TECH FIG 1 • Exposure of the femur in a patient who has sustained a periprosthetic fracture.

PROXIMAL FEMORAL REPLACEMENT

- If the femur is intact, an osteotomy to split the proximal femur may be required to facilitate removal of the previous prosthesis or hardware.
- A transverse osteotomy first is made in the host bone at the most proximal area of bone with good circumferential quality.
- Because the outcome of this procedure is influenced directly by the length of the remaining femur, maximum length of the native femur is maintained at all costs.\(^1\)
- We then use a longitudinal Wagner type of coronal plane osteotomy to split the proximal femur if the bone quality is poor.
- Soft tissue attachments to the proximal femur—particularly the abductor mechanism, if present—should be retained if at all possible. Once the femur is exposed, the distal portion of the canal is prepared by successive broaching. The cancellous bone, when present, is preserved for better cement interdigitation.
- After completion of femoral preparation and determination of the size of best-fit broach, trial components are inserted, and the stability of the hip is examined.
- A distal cement restrictor is used whenever possible. The restrictor is introduced and advanced distally to allow for at least 2 cm of bone cement at the tip of the stem.
- The cement is pressurized and the final component implanted, with care taken to ensure that the porous coated portion of the stem is placed directly and firmly against diaphyseal bone with no interpositioning cement.
- The prosthesis can be assembled and then cemented distally or, alternatively, the stem can be cemented and then the body assembled onto it.

TECH FIG 2 • Demonstration of how the rotational positioning or version of the femoral component is determined. The version of the femoral stem is judged by appropriate positioning of the knee.
TOTAL FEMUR REPLACEMENT

- Indications for total femoral replacement are rare and generally include inadequate length (less than 10 cm) or such poor quality of distal femoral bone that fixation of a femoral stem is precluded. In most cases, the distal femur is of adequate length and quality to allow secure fixation.
- Total femoral replacement includes an arthrotomy of the knee to allow prosthetic replacement of the knee.
- Once exposure of the femur is completed using a lateral vastus reflecting approach, the entire femur is split longitudinally in the coronal plane.
- Again, even if it is of extremely poor quality, as much of the bone with its soft tissue attachment as possible is retained.
- The subvastus approach is extended to include a lateral or medial arthrotomy of the knee and eversion of the patella.
- The amount of tibial bone resected is kept to a minimum, but it must be of adequate thickness to allow implantation of the components and insertion of polyethylene without elevating the joint line. The tibia is prepared in the same manner as for total knee arthroplasty. Once appropriate tibial component size is determined, preparation of the tibia followed by insertion of the trial component is carried out.
- A full-length trial femur is assembled, ensuring that appropriate limb length is restored. Unless constrained liners are to be used, we prefer to use a large femoral head size to improve arc of motion and minimize instability.
- The tibial polyethylene usually is between 15 and 20 mm thick, but it may be necessary to adjust the thickness to obtain appropriate length of the extremity and restore the joint line.
- A linked articulated knee design is necessary because of loss of the stabilizing ligamentous structures. Once the prosthesis is assembled, a trial reduction is carried out and tested for stability.
- We usually do not resurface the patella unless severe wear of the articular cartilage is noted.

DETERMINATION OF LIMB LENGTH

- The length of the femoral component is determined through careful preoperative planning and intraoperative assessment.
- Two methods may be used for proper leg length determination.
  - The first method is to apply traction to the limb with measurement from the cup to the host bone osteotomy site (for proximal femoral replacement).
  - The second and preferred method is to place a Steinmann pin in the iliac crest to measure a fixed point on the femur before dislocation.
- With the long-stem trial prosthesis in place, proper leg length can be accurately restored. For patients with total femur replacement, radiographs of the opposite, normal femur may be obtained preoperatively and used for accurate templating for length.
- The length of the prosthesis usually equals the length of the bone being resected, although in many patients the integrity of the bone has been breached and the anatomy markedly altered.
- Ultimately, the femoral prosthesis length depends on the soft tissue tension about the hip. Balancing tension, restoration of limb length, and avoiding excessive tension on the sciatic nerve are of utmost importance if complications are to be avoided.

ACETABULAR RECONSTRUCTION

- The acetabulum is exposed at the beginning of the operation and examined carefully. If a previous acetabular component is in place, the stability and positioning of the component are scrutinized.
- If the component is appropriately placed and stable, it is left in place, and the liner is exchanged. If a previous acetabular component is not in place, a new component is inserted in a press-fit manner with screw fixation.
- More complex acetabular reconstruction, eg, the use of an antiprotrusio cage, occasionally is needed.
- The type of acetabular liner is determined after reconstruction of the femur has been completed, because it may be necessary to use constrained liners in patients with poor soft tissue tension and a high probability of instability.
- The constrained liners can be either snap-fit or cemented into the shell, depending on the type of the acetabular component implanted. In our experience, constrained liners are required in approximately half of patients receiving a megaprosthesis.
- Our absolute indication for the use of a constrained liner is for patients with properly positioned components and equal or near equal leg length who have intraoperative instability secondary to soft tissue deficiency.
CLOSURE

- The femur, however poor in quality, is maintained and wrapped around the megaprostheses at the conclusion of implantation.
- The muscle–tendon attachments are preserved whenever possible.
- The soft tissues—especially the abductors, if present—are meticulously secured to the prosthesis (TECH FIG 3).
- Multiple loops of nonabsorbable sutures are passed around the trochanter remnant and the attached soft tissue.
- The leg is brought to abduction and the trochanter firmly fixed onto the proximal portion of the prosthesis by passing the sutures through the holes in the prosthesis or around the proximal body and the deep tissues.
- We occasionally suture the abductors to the vastus lateralis, the tensor fascia lata, or the host greater trochanter, if available.
- Two surgical drains are inserted before the wound is closed in layers using interrupted resorbable sutures. Meticulous skin closure, with excision of hypertrophic prior scar, if necessary, is carried out to minimize postoperative wound drainage.

PEARLS AND PITFALLS

**Preoperative**
- Examine the patient thoroughly. Note previous scars, the status of the abductors, and limb length.
- Discuss the procedure with the patient and help him or her form realistic expectations.
- Perform detailed preoperative templating.
- Have the company representative available to review your templating and to ensure that correct components, and neighboring sizes, are available on the day of surgery.
- Ask for an experienced scrub and anesthetic team.

**Intraoperative**
- Minimize soft tissue dissection off the native bone and retain as much of the host bone as possible.
- Restore appropriate leg length and soft tissue tension.
- Have a low threshold for the use of constrained liners.
- Ensure good hemostasis and perform a meticulous wound closure.

POSTOPERATIVE CARE

- Intravenous prophylactic antibiotics are given and maintained until final cultures are obtained. Thromboembolic prophylaxis also is administered for 6 weeks.
- Patients are allowed to commence protected weight bearing on postoperative day 1.
- We recommend the use of an abduction orthosis for all patients and protected weight bearing for 12 weeks, until adequate soft tissue healing occurs.
- Patients usually are able to ambulate with the use of a walking aid during this time. Patients receiving total femur replacement may require the use of continuous passive motion machines for rehabilitation of the knee replacement.
- Daily physical therapy for assistance with ambulation and range-of-motion exercise for the knee are recommended.

OUTCOMES

- The first experience with use of a megaprostheses for reconstruction of the proximal femur in nonneoplastic conditions was reported in 1981. Although all 21 patients in that cohort had significant pain relief, there were two failures. One patient required acetabular component revision, and the
second patient needed revision of the femoral component for recurrent instability.

- Malkani et al\textsuperscript{16} reported the outcome of 50 revision hip arthroplasties using prosthetic femoral replacement in 49 patients with nonneoplastic condition. All patients had massive proximal bone loss, and some patients had multiple failed attempts with other reconstructive procedures. The mean follow-up was 11 years. The mean preoperative Harris hip scores of 43 ± 13 points improved significantly, to 80 ± 10 points at 1 year, and had improved to 76 ± 16 points at the latest follow-up. Before surgery, 86% of the patients had moderate to severe pain. Pain relief was achieved in 88% of patients at 1 year and 73% of patients at the latest follow-up. However, there was some deterioration in all parameters with time.

- Detailed radiographic analysis revealed an increase in the incidence of progressive radiolucent lines on the femoral and acetabular sides. Progressive radiolucency was seen around 37% of the acetabular components and 30% of the femoral components. Aseptic loosening constituted the main reason for revision surgery. Using revision as an end point, overall survivorship in the aforementioned series was 64% at 12 years. The most common complication was dislocation, with an overall rate of 22%.

- The results of 11 patients undergoing total femur replacement at the Mayo Clinic were recently evaluated. Six of these patients had total femur reconstructions performed for multiply failed ipsilateral TKA and total hip arthroplasty. Five patients, four of whom had pathologic fractures, underwent total femur replacement as limb salvage for musculoskeletal malignancy. Of the six patients who had total femoral replacement for failed arthroplasties, hip instability in two necessitated conversion to a constrained acetabular liner. Of two patients with previous infections, one developed recurrent infection despite staged total femoral reimplantation, and one has an elevated sedimentation rate on chronic antibiotic suppression but no evidence of clinical infection. All patients ambulated with either a walker or a cane. Of the five patients who had total femoral replacement for treatment of tumor, one developed hip and knee pain within 3 years, had wear of the knee hinge bushings, and is seeking disability. One patient developed wound dehiscence and sepsis in the postoperative period and died. Two patients ambulate with a cane and three without the routine use of any gait aids.

- Klein et al\textsuperscript{11} reported the outcomes of revision total hip arthroplasty with use of a proximal femoral replacement in a cohort of patients who had Vancouver type B3 periprosthetic fracture. A modular femoral replacement with proximal porous coating had been used in all cases. Twenty-one patients (mean age 78.3 years; range 52 to 90 years) were included in the cohort. At follow-up (mean 3.2 years) all but one of the patients were able to walk and had minimal to no pain. Complications included persistent wound drainage that was treated with incision and drainage (two hips), dislocation (two hips), refracture of the femur distal to the stem (one hip), and acetabular cage failure (one hip).

- Parvizi et al\textsuperscript{21} reported on 48 patients from two institutions (mean age 73.8 years) who had undergone placement of a modular megaprosthesis, with or without bone-grafting. The indications for proximal femoral replacement were as follows:
  - Periprosthetic fracture: 20 patients
  - Reimplantation because of a deep infection: 13 patients
  - Failed arthroplasty: 13 patients

- Malkani et al\textsuperscript{16} reported the outcome of 50 revision hip arthroplasties using prosthetic femoral replacement in 49 patients with nonneoplastic condition. All patients had massive proximal bone loss, and some patients had multiple failed attempts with other reconstructive procedures. The mean follow-up was 11 years. The mean preoperative Harris hip scores of 43 ± 13 points improved significantly, to 80 ± 10 points at 1 year, and had improved to 76 ± 16 points at the latest follow-up. Before surgery, 86% of the patients had moderate to severe pain. Pain relief was achieved in 88% of patients at 1 year and 73% of patients at the latest follow-up. However, there was some deterioration in all parameters with time.

- Detailed radiographic analysis revealed an increase in the incidence of progressive radiolucent lines on the femoral and acetabular sides. Progressive radiolucency was seen around 37% of the acetabular components and 30% of the femoral components. Aseptic loosening constituted the main reason for revision surgery. Using revision as an end point, overall survivorship in the aforementioned series was 64% at 12 years. The most common complication was dislocation, with an overall rate of 22%.

- The results of 11 patients undergoing total femur replacement at the Mayo Clinic were recently evaluated. Six of these patients had total femur reconstructions performed for multiply failed ipsilateral TKA and total hip arthroplasty. Five patients, four of whom had pathologic fractures, underwent total femur replacement as limb salvage for musculoskeletal malignancy. Of the six patients who had total femoral replacement for failed arthroplasties, hip instability in two necessitated conversion to a constrained acetabular liner. Of two patients with previous infections, one developed recurrent infection despite staged total femoral reimplantation, and one has an elevated sedimentation rate on chronic antibiotic suppression but no evidence of clinical infection. All patients ambulated with either a walker or a cane. Of the five patients who had total femoral replacement for treatment of tumor, one developed hip and knee pain within 3 years, had wear of the knee hinge bushings, and is seeking disability. One patient developed wound dehiscence and sepsis in the postoperative period and died. Two patients ambulate with a cane and three without the routine use of any gait aids.

- Klein et al\textsuperscript{11} reported the outcomes of revision total hip arthroplasty with use of a proximal femoral replacement in a cohort of patients who had Vancouver type B3 periprosthetic fracture. A modular femoral replacement with proximal porous coating had been used in all cases. Twenty-one patients (mean age 78.3 years; range 52 to 90 years) were included in the cohort. At follow-up (mean 3.2 years) all but one of the patients were able to walk and had minimal to no pain. Complications included persistent wound drainage that was treated with incision and drainage (two hips), dislocation (two hips), refracture of the femur distal to the stem (one hip), and acetabular cage failure (one hip).

- Parvizi et al\textsuperscript{21} reported on 48 patients from two institutions (mean age 73.8 years) who had undergone placement of a modular megaprosthesis, with or without bone-grafting. The indications for proximal femoral replacement were as follows:
  - Periprosthetic fracture: 20 patients
  - Reimplantation because of a deep infection: 13 patients
  - Failed arthroplasty: 13 patients

- Nonunion of an intertrochanteric fracture: 1 patient
- Radiation-induced osteonecrosis with a subtrochanteric fracture: 1 patient
- Three patients died before the minimum 2-year follow-up interval had elapsed, and two additional patients were lost to follow-up. The mean duration of follow-up for the remaining study group of 43 patients was 36.5 months. At the time of follow-up, there was a significant improvement in function as measured with the Harris hip score. The major complications were instability (8 patients), failure of the acetabular component (4 patients), and infection (1 patient). Of the eight patients with instability, six required reoperation because of dislocation and two, who had subluxation, required no further intervention. With revision used as the end point, the survivorship of the implant was 87% at 1 year and 73% at 5 years.

### COMPLICATIONS

- The major complications encountered following the use of a megaprosthesis are early dislocation and aseptic loosening. The cause of instability in this group of patients is multifactorial. First, these patients often have had multiple previous reconstructive procedures that have led to compromised abductors around the hip. Furthermore, the inability to achieve a secure repair of the residual soft tissues to the metal prosthesis predisposes these patients to instability.\textsuperscript{9} The problem is further exacerbated in patients in whom the proper leg length and appropriate soft tissue tension is not achieved.

- We have implemented changes in our practice to minimize instability. These include the use of constrained cups in selective cases, routine use of a postoperative abduction brace, and augmentation of the proximal bone with the use of strut allograft that imparts more rigidity for soft tissue attachment. It is conceivable that the problem of soft tissue to metal attachment may be better addressed in the future with the use of trabecular metals such as tantalum, with its excellent potential for soft tissue ongrowth. The use of a modular prosthesis has provided a better strategy for dealing with this problem. The proximal femoral bone, however poor in quality, should be retained and reapproximated to the prosthesis to minimize dislocation. In addition, all efforts should be made to achieve equal limb lengths and to obtain acceptable soft tissue tension. Another important factor in the prevention of instability is the use of larger femoral heads in elderly patients who have a low level of activity if instability is encountered intraoperatively.

- The other common complication of megaprosthesis reconstruction is the relatively high incidence of acetabular and femoral radioluency in most reported studies. The reason for this complication lies in the biomechanical aspect of this reconstructive procedure. The diaphyseal cement fixation predisposes the bone-cement-prosthesis unit to high torsional and compressive stresses, leading to early loosening. Cemented long-stem revision implants are known to have limited success and currently are recommended only for elderly and sedentary patients.\textsuperscript{18} As would be expected, the incidence of radiolucency after the use of press-fit or proximally or extensively coated ingrowth stems is markedly lower than that with a megaprosthesis.\textsuperscript{2,20}

- The incidence of radiolucency after megaprosthesis reconstruction at our institution has declined somewhat. This may be the result of improved cementing techniques, namely, the use of pulse lavage and plugging of the canal for better cement
interdigitation. However, the more likely explanation for the reduction in the incidence of radiolucency is that we have narrowed the indications for the use of megaprosthesis to elderly and sedentary patients who place lower demands on the prosthesis.

REFERENCES

DEFINITION
- Acetabular bone loss remains a challenge to the joint reconstruction surgeon.
- Bone loss may be the result of trauma, acetabular dysplasia, tumor, infection, implant loosening, or osteolysis.
- Primary reconstruction methods often are inadequate to restore bone loss.
- Acetabular impaction grafting restores bone stock by using tightly impacted, well-contained cancellous bone graft.
- The goal of impaction bone-grafting is to achieve immediate implant stability with the use of compacted, morselized bone graft. In turn, this allows the restoration of bone stock through bone remodeling.
- Impaction bone grafting is suitable for simple cavitary defects as well as extensive segmental defects.
- Stainless steel mesh is used to convert segmental defects (medial wall or peripheral) into contained cavitary defects suitable for impaction grafting.
- Impacted bone graft provides an excellent bed for cement interdigitation, which confers immediate mechanical stability and acts as a substrate promoting bone remodeling, allowing bone stock restoration.
- Acetabular impaction grafting has shown good long term results.\textsuperscript{7-10}
- Standard implants and current cement techniques often are used.

ANATOMY
- The acetabulum is a complex three-dimensional structure.
- It is important to identify relevant landmarks intraoperatively, such as the transverse acetabular ligament, medial wall, anterior and posterior walls and columns, and superior dome (FIG 1).
- Bone impaction grafting combined with a cemented polyethylene cup allows for the restoration of the hip center and normal hip biomechanics.

PATHOGENESIS
- Animal studies show that impacted, morselized fresh-frozen allograft bone incorporates into new bone.\textsuperscript{6}
- Twenty-four acetabular bone biopsy specimens were obtained from 20 patients who had undergone acetabular reconstruction with impaction bone grafting.\textsuperscript{11}
  - Biopsy specimens were obtained at 3 months to 15 years.
  - Histology showed rapid revascularization of the graft followed by osteoclastic resorption and woven bone formation on the graft remnants.
  - A mixture of graft, new bone, and fibrin remodeled completely into a new trabecular structure, with normal lamellar bone and only scarce remnants of graft material.
- Localized areas of nonincorporated bone graft surrounded by fibrous tissue remained, irrespective of the follow-up period.
- Large nonincorporated fragments of cartilage also were found, particularly in cases in which femoral head bone chips were produced by a bone mill.
- Despite the contact between bone graft and cement, the bone graft retains its biologic and mechanical viability and healing potential.\textsuperscript{5}

NATURAL HISTORY
- Reports on acetabular impaction grafting show promising intermediate and long-term results.\textsuperscript{4,7-10}

PATIENT HISTORY AND PHYSICAL FINDINGS
- It is important to obtain a thorough history from the patient with a failed acetabular component.
- A history of persistent infection should be ruled out.
- Physical examination should include examination of previous incisions, sinus tracts, range of motion, leg-length discrepancy, neurovascular status, and contractures.
- Records of previous surgeries should be obtained.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- The initial diagnostic imaging examination should begin with standard AP pelvis and AP and lateral radiographs of the affected hip.
A CT scan may be useful in identifying bone loss and structural defects.

The actual bone defects or bone loss may be more severe than preoperative radiographic studies reveal.\(^\text{12}\)

A preoperative work-up for infection should be performed.

Laboratory studies, including a complete blood cell count with differential, erythrocyte sedimentation rate, and C-reactive protein, should be obtained.

If laboratory values are elevated or suspicious for infection, a fluoroscopic guided aspiration should be performed and sent for cell count, Gram stain, and cultures to rule out infection.

**DIFFERENTIAL DIAGNOSIS**

Alternative methods of fixation include cemented acetabular revision, revision with structural allograft, uncemented acetabular components with structural allograft, uncemented components with metal augments, jumbo acetabular components, and trabecular metal acetabular components.

In cases of pelvic discontinuity or severe anterior or posterior column defects, alternative techniques of reconstructions such as cages, plates and screws, or trabecular metal implants may be necessary.

**NONOPERATIVE MANAGEMENT**

No nonoperative techniques are available for reconstruction of the failed acetabulum.

**SURGICAL MANAGEMENT**

**Preoperative Planning**

Precise preoperative templating is necessary to restore the acetabular component to its anatomic position to reestablish the native hip center.

**Positioning**

The patient is positioned according to the surgeon’s preference and planned surgical approach. This technique is applicable to most patient positions and surgical techniques.

**Approach**

Any surgical approach that allows full acetabular exposure can be used. It is important that the surgeon use an approach that is both familiar and extensile.

Wide exposure and identification of the major landmarks of the acetabulum are necessary.

**ACETABULAR EXPOSURE**

A wide exposure of the acetabulum is necessary. The femur may be mobilized or a femoral osteotomy performed to improve acetabular exposure. Removal of the femoral stem may be necessary to gain unimpeded exposure of the acetabulum.

- Circumferential capsulotomy often is necessary.
- Iliopsoas release may be necessary.

The previous acetabular components are removed using traditional implant removal techniques and care must be taken to avoid additional bone damage.

Any residual cement must be removed.

Fibrous tissue and necrotic bone are débrided until viable bleeding bone is encountered.

Acetabular bone defects are identified.

**ACETABULAR PREPARATION**

An acetabular reamer is used to remove sclerotic cortical bone to expose bleeding trabecular bone. Multiple drill holes (2 mm) may be used to create bleeding in areas of extremely sclerotic bone.

The acetabulum is irrigated with pulsatile lavage.

The anatomic position for the acetabular component is identified.

- Because there may be severe anterior, posterior, or superior bony deficiencies, this is best done by first locating the inferior portion of the acetabulum and transverse acetabular ligament.
- A trial acetabular component may be used to identify bone deficiencies and estimate the amount and location of bone graft needed.

Segmental defects are converted into cavitary defects with flexible wire mesh and screws (X-change Revision Instrument System, Stryker Orthopaedics, Mahwah NJ).

This mesh is precontoured but may be trimmed and adapted to fit the identified acetabular defects.

Medial segmental defects may be covered with metal mesh.

- Usually the mesh is stable without screws; however, small screws may be used for initial mesh stability.
- If the medial wall is found to be intact but weak, mesh may be used to support or prevent dorsal graft migration during impaction (TECH FIG 1A).

Peripheral wall defects are identified.

Complete exposure of the peripheral rim with subperiosteal dissection is performed to avoid injury to surrounding neurovascular structures such as the superior gluteal nerve and vessels.

Peripheral mesh is applied to the outer side of the acetabular rim with bicortical screws at a minimum of three points (TECH FIG 1B).

If necessary, the wire mesh may be applied to the inner surface of the acetabulum and fixed with screws.
**TECH FIG 1** - After removal of a failed acetabular component, stainless steel wire mesh and screws are used to reconstruct a central medial wall defect (A) and a peripheral superolateral defect (B).

**PREPARATION OF BONE GRAFT**
- Allograft bone from fresh-frozen femoral heads is used. If autogenous bone is available, this may be mixed with the allograft bone. Usually at least two femoral heads are needed. Large defects require more graft material. The allograft is thawed and débrided of all soft tissue before it is used.
- A 7- to 10-mm bone chip is recommended, in contrast to the smaller bone graft size used with femoral impaction grafting.
- Soft tissue and cartilage must be removed from the bone graft.
- The femoral head is divided into four parts with a saw and morselized using a rongeur into 7- to 10-mm bone chips.
- Alternatively, commercially available bone mills may be used. Most bone mills produce graft sized for femoral impaction grafting, which may be too small for acetabular impaction grafting.
- Larger bone graft size and the removal of excess fat and soft tissue with mechanical débridement and warm saline lavage enhances initial stability.

**ACETABULAR BONE RECONSTRUCTION**
- The acetabulum is irrigated with pulsatile lavage.
- Small cavitary defects are first packed with graft. Then bone graft is impacted into the acetabular cavity layer by layer to construct an anatomically located neoeacetabulum.
- Vigorous impaction using specialized impactors is necessary. A small impactor should be used initially for graft impaction and gross acetabular reconstruction, and then progressively larger impactors should be used to shape the neoeacetabulum (TECH FIG 2).
- Reverse reaming with an acetabular reamer should be avoided, because this technique has shown inferior results.
- When performed correctly, the bone graft will be stable in the acetabulum even after the impactors are removed.
- At least 5 mm of impacted graft is necessary to prevent overpenetration of cement into the host bone–graft interface.
- The last impactor should be approximately 4 mm larger than the acetabular cup to be placed. This allows for an adequate cement mantle.
- Once impacted, the bone graft and bed should not be irrigated with pulsatile lavage.
Cemented Cup Insertion

- The acetabular bed is thoroughly dried. Hydrogen peroxide may be used to clean and dry the acetabular bed.
- Vacuum-mixed antibiotic-loaded cement is prepared using the technique of choice. While still in a relatively viscous state, the cement is placed in the acetabular bed. A cement pressurizer is used to introduce the cement into the impacted bone graft (TECH FIG 3A).
- An all-polyethylene cup is implanted using the alignment guide and insertion handle of the surgeon’s choice (TECH FIG 3B). The cup is held in position with a cup pusher until the cement hardens.

TECH FIG 2 • A. The defect is filled with allograft bone chips. B. The bone chips are vigorously impacted using specialized bone impactors of progressively larger size.

TECH FIG 3 • A. After a stable bone graft thickness of at least 5 mm has been obtained, antibiotic-impregnated cement is pressurized into the bone graft. B. An all-polyethylene cup is then inserted into the cement mantle.
Commercial bone mills often produce smaller graft sizes.

Sclerotic bone should be reamed or drilled with a 2-mm drill.

Bone graft should be 7 to 10 mm³. Overimpaction may cause fractures.

Remove all soft tissue and cartilage.

Optimal cup placement is necessary to restore the anatomic center, thereby limiting instability.

Reverse reaming with acetabular reamers should be avoided.

Fresh-frozen bone femoral head is the ideal graft.

Wide acetabular exposure is necessary to identify and contain bone defects with wire mesh. Be cautious of neurovascular structures.

Interval-appropriate radiographs are recommended.

Complications generally related to revision hip arthroplasty, such as infection, instability, hematoma, and neurovascular injury, can occur.

Wide acetabular exposure puts neurovascular structures such as the superior gluteal nerve and vessels at risk.

Intraoperative fractures may occur due to overimpaction of the bone graft.

Potential infection or graft-versus-host disease theoretically may occur as a result of the bone graft material. Eradication of infection may require resection arthroplasty.

PEARLS AND PITFALLS

Acetabular exposure

- Wide acetabular exposure is necessary to identify and contain bone defects with wire mesh. Be cautious of neurovascular structures.

Acetabular preparation

- Sclerotic bone should be reamed or drilled with a 2-mm drill.

Bone graft preparation

- Fresh-frozen bone femoral head is the ideal graft.
- Remove all soft tissue and cartilage.
- Bone graft should be 7 to 10 mm³.
- Commercial bone mills often produce smaller graft sizes.
- Irrigate graft with warm saline prior to impaction.
- Do not irrigate the graft once it is impacted.

Acetabular bone reconstruction

- Vigorous impaction with specially designed impactors is necessary to provide initial mechanical stability of the graft.
- Overimpaction may cause fractures.
- Reverse reaming with acetabular reamers should be avoided.

Cemented cup insertion

- Optimal cup placement is necessary to restore the anatomic center, thereby limiting instability.

REFERENCES

DEFINITION

- Acetabular bone deficiency may occur primarily (e.g., dysplasia, inflammatory arthritis, seronegative arthropathy) or secondarily (e.g., aseptic or septic loosening of acetabular components, osteolysis, trauma, iatrogenic loss during removal of well-fixed components).
- The use of antiprotrusio cages is indicated in situations where an uncemented porous-coated acetabular component will not gain reliable initial stability.

ANATOMY

- The confluence of the ilium, the ischium, and the pubis forms the hemispherically-shaped acetabulum, each contributing to the anterior and posterior walls and columns.
- Surgical landmarks include the anterior and posterior walls, dome, and medial wall “teardrop.”
- The acetabulum is normally oriented with 45 degrees of inclination and 15 degrees of anteversion relative to the pelvic plane.

PATHOGENESIS

- Acetabular bone deficiency may occur primarily due to dysplasia. This type of deficiency usually does not require the use of an antiprotrusio cage.
- Certain conditions (e.g., rheumatoid arthritis, juvenile rheumatoid arthritis, ankylosing spondylitis, Paget disease) may predispose to acetabular protrusion but usually do not require the use of an antiprotrusio cage.
- The antiprotrusio cage is used most often in cases of secondary bone stock deficiency so massive that the use of a cementless press-fit acetabular component is precluded.

NATURAL HISTORY

- The natural history of massive acetabular bone defects that would require an antiprotrusio cage is not known. Patients usually require revision surgery to return to functional activities.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The history should be directed to determine whether the source of pain is extrinsic or intrinsic.
- The patient’s pain may be extrinsic (e.g., lumbar radiculopathy, intrapelvic pathology), in which case revision surgery may fail to relieve pain completely.
  - Pain usually, but not always, is located in the groin.
  - Infection always must be assessed with careful questioning about previous infections, fevers, chills, wound drainage, and pain at rest.
  - Start-up pain is a characteristic indication of loosening.
- Medical comorbidities must be assessed to determine the presence of any that may compromise the outcome of the surgery or place the patient at increased risk of complications.
  - The skin should be inspected visually for placement of prior incisions and signs of infection.
  - The appropriate incision for the surgical approach must be used with an adequate (6 cm) skin bridge.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Plain radiographs, including AP of the pelvis and AP and true lateral of the hip should be obtained to classify bone loss and to adequately preoperatively plan (FIG 1).
- CT scans may be used to assess the remaining bone stock.
  - This is especially important in cases of superior or posterior bone loss that may require allograft reconstruction.
  - The CT scan can help determine the need to have allograft bone available to reconstruct the defect and may help to dictate the approach if a posterior column reconstruction or plating is necessary.
- CT scans with intravascular contrast are useful in situations in which a prior implant is medial to Kohler’s line and proximity of the implant to the vessels and intra-abdominal contents is unknown.
- Erythrocyte sedimentation rate and C-reactive protein are useful screening tools to detect infection.
- Aspiration of the hip to assess for infection is valuable if either the erythrocyte sedimentation rate, C-reactive protein, or clinical suspicion is elevated.
- Nuclear medicine studies such as technetium Tc 99m diphosphonate in combination with gallium citrate, indium 111–labeled leukocyte scans, positron emission tomographic scans with 18F-fluorodeoxyglucose (PET-FDG), and sulfur colloid scans may help differentiate aseptic from septic loosening.

DIFFERENTIAL DIAGNOSIS

- The following conditions may contribute to pain and may be the cause of continued pain after the surgery:
  - Lumbar radiculopathy
  - Spinal stenosis
  - Sacroiliac degenerative joint disease
  - Intra-abdominal pathology
  - Intrapelvic pathology
  - Neuropathy
  - Meralgia paresthetica
  - Complex regional pain syndrome
  - Vascular claudication
  - Primary bone tumors
  - Metastasis

NONOPERATIVE MANAGEMENT

- Nonoperative management of severe acetabular bone loss is reserved for those patients for whom surgical management is contraindicated. These include patients with substantial medical comorbidities and patients with active infection.
SURGICAL MANAGEMENT

- Surgical management begins with preoperative planning.
- The radiographs are assessed and it is determined whether the defect can be reconstructed with a cementless acetabular component or will require an antiprotrusio cage.
- The surgical approach is planned.
  - If posterior column plating is anticipated, a posterior approach is indicated.
  - If this is not required, a direct lateral or posterior approach may be used, according to the surgeon’s preference.
- The acetabulum is exposed, bone loss is assessed, and the determination as to the appropriate reconstructive choice is made.

Preoperative Planning

- Planning for the antiprotrusio cage begins with appropriate radiographs.
- The radiographs allow for classification of the defect and aid in planning for the reconstruction.
- We have found the Paprosky classification to be helpful in defining bone deficiency and in predicting the method of reconstruction (FIG 2).
- Paprosky type 1 acetabular defects have minimal bone loss and usually can be reconstructed using just a cementless component.
- Type 2A defects have an intact superior rim, and the acetabulum is oval in shape. The anterior and posterior columns are intact. The implant has migrated less than 2 cm. These defects may be reconstructed with so-called “jumbo” cups or cementless reconstruction with additional bone grafting or trabecular metal augments. The socket also may be placed in a more superior position to attain greater contact with host bone.
- Type 2B defects are similar to type 2A defects, with the exception of loss of the superior rim. The implant has migrated less than 2 cm. The superior rim can be reconstructed with an uncemented socket in association with bone grafting or trabecular metal augmentes.
- Type 2C defects involve medial bone loss with intact anterior and posterior columns. The medial bone loss may be reconstructed with bone grafting or trabecular metal augmentes and an unce-mented socket.
- Type 3A defects generally migrate more than 2 cm superolaterally. The medial wall and ischium usually are still present, but damaged. These defects can be reconstructed with bone grafting or trabecular metal augmentes and an unce-mented socket.
- Type 3B defects generally migrate more than 2 cm supra-medially. There is loss of the teardrop and severe damage to the ischium. Pelvic discontinuity should be suspected. These defects can be reconstrucrted with bulk allograft, trabecular metal, antiprotrusio cage, or a combination. Posterior column plating may be needed in cases of acute discontinuity. If this is a possibility, then a posterior approach should be selected.
- Pelvic discontinuity should be suspected if a fracture is noted that involves both the anterior and posterior columns, the inferior hemipelvis has migrated medial to the superior hemipelvis, or the inferior hemipelvis is rotated in relation to the superior hemipelvis.
- Large posterior column defects may predispose to cage failure, and reconstruction of the defect should be included in preoperative planning.
- An appropriate device should be selected.

FIG 1 • AP radiograph of the hip demonstrates medial migration of the acetabular cup with significant loss of acetabular bone stock.

FIG 2 • Preoperative radiographs of a patient with severe acetabular bone loss due to superior and medial migration of construct as well as pelvic discontinuity (Paprosky type 3B defect). An AP radiograph of the pelvis (A), an AP view of the hip (B), and a frog-leg lateral view of the hip (C) are obtained. Occasionally more specialized views of the pelvis, such as the Judet view, may be necessary to assess integrity of the acetabular columns.
The flanges should be malleable to allow the cage to be shaped to the bone.
- The implant must have sufficient strength.
- We believe that an inferior flange that gains fixation in or on the ischium is superior to a hook that gains fixation on the teardrop.

**Positioning**
- The patient is positioned according to surgeon preference, as dictated by the surgical approach. The hip should be draped in such a fashion as to allow wide surgical exposure.

**Approach**
- The surgeon should select a posterior approach if he or she anticipates the need for posterior column plating or reconstruction. Otherwise, the surgeon should select the approach that is most familiar and comfortable.
- A trochanteric ostetomy, either conventional or extended, may improve exposure of the acetabulum and pelvis.
- Exposure of the sciatic nerve (posterior approach) is left to the judgment of the surgeon.

**ACETABULAR EXPOSURE**
- The acetabulum is exposed, and the failed construct and any soft tissue that interferes with visualization should be retracted or removed (TECH FIG 1A–E).
- The anterior and posterior walls/columns, superior dome/rim, medial wall, teardrop, and ischium are identified, and bone loss is noted (TECH FIG 1F–H).

**TECH FIG 1** • Acetabular exposure.
A. The acetabulum after exposure with a direct lateral (modified Hardinge) approach in the supine position. B. The polyethylene cup is removed. C. Unstable cage construct is removed in one piece with cement. D,E. Failed construct after removal. Once all material is removed, the acetabular landmarks are clearly exposed and evaluated: teardrop (F), posterior column (G), superior dome/rim (H).
INTRAOPERATIVE DETERMINATION OF RECONSTRUCTIVE TECHNIQUE

- The remaining bone stock is assessed and corroborated with the preoperative assessment of bone loss.
  - Paprosky types 1, 2A, 2B, 2C, and 3A defects usually can be reconstructed with an uncemented acetabular component with or without bone grafting or trabecular metal augments.
  - All acetabuli, especially Paprosky type 3B defects, should be tested for pelvic discontinuity.
- If a pelvic discontinuity exists (TECH FIG 2), the surgeon may then elect to use an antiprotrusio cage with or without posterior column plating or additional bone grafting.
  - Alternatively, the surgeon may elect to distract the discontinuity with an uncemented socket and bridge the defect in this manner.
- The acetabulum should be assessed for the remaining bone’s ability to support an uncemented component. To support an uncemented cup, the remaining bone stock should allow for at least partial inherent stability of the reamer or trial.
  - Reamers or trials that are inherently unstable may not be appropriate for cementless reconstruction.

- The reamers are not used initially to shape the acetabulum but, rather, are used to assess the ability of the remaining bone to support a socket.
  - If it is determined that the remaining bone stock cannot support a socket, then an antiprotrusio cage should be used.

BONE PREPARATION

- The ilium must be exposed with care to avoid the superior gluteal neurovascular bundle (TECH FIG 3A).
- The size of the defect can be assessed with a standard acetabular reamer. The reamer can then be used to remove small amounts of bone that may prevent complete seating of the cage (TECH FIG 3B).
  - It should not be necessary to remove significant bone, because the indication for use of this device is severe bone loss.
  - The outer diameter of the reamer that best fits the acetabulum determines the outer diameter of the cage.
  - The trial cage or the actual implant can be used to determine the removal of small amounts of bone that interfere with complete seating of the cage (TECH FIG 3C).

BONE GRAFT AND TRABECULAR METAL AUGMENTATION

- The cage may not be stable in situations with severe superior dome or posterior bone loss.
  - It may be necessary to augment the acetabulum with either structural or particulate bone graft (TECH FIG 4) or trabecular metal to provide the cage with support.
  - Severe superior dome or posterior wall or column bone loss may be reconstructed with structural allograft.
Bone graft and trabecular metal augmentation.

A. Allograft cancellous bone is placed into the prepared acetabulum. B. Large reamer is used in reverse to crush and distribute the graft.

TECH FIG 4

CAGE IMPLANTATION

- The ischial flange can be placed on or in the ischium (TECH FIG 5A, B).
  - The advantage of placing the flange on the ischium is that screws can be used to fix the cage to the ischium (TECH FIG 5C, D).
  - The advantage of blade-plating the flange in the ischium is avoidance of the sciatic nerve (TECH FIG 5E).
  - Both methods allow for stable fixation.

- The cage is shaped to the contour of the ilium and ischium while allowing for seating of the socket portion of the cage into the remaining acetabulum. Usually the ischial flange must be bent laterally to follow the contour of the ischium.
- The ischial flange is fixed to or in the ischium using the surgeon’s preferred method.

TECH FIG 5

- Cage implantation. A. The cage is shown in the orientation in which it will be inserted. B. Cage being inserted. C, D. Screw fixation to ischium. E. Blade plate fixation of the ischium flange. (continued)
Chapter 10 REVISION THA WITH ACETABULAR BONE LOSS: ANTI-PROTRUSION CAGE

The socket portion of the cage must be fully seated within the acetabulum to maximize the stability of the construct.

The flange must be contoured to the ilium to minimize cage motion. Usually this requires the flange to be bent medially with some rotation.

Once the cage is appropriately contoured to the ischium, ileum, and acetabulum and fixed to the ischium, it is fixed with screws through the dome of the cage.

Fixation usually can be obtained in the posterior and anterior columns, with care to stay within the recognized safe zones.

Additional screws should then be passed through the superior flange into the ilium (TECH FIG 5F,G). The number of screws is limited by the amount of bone that can safely provide fixation.

A polyethylene liner is then cemented into the cage construct.

The cement is placed in the socket and pressurized (TECH FIG 5H–K).

A liner designed for cementation or a liner appropriately modified for cementation is then cemented into place in the appropriate position (TECH FIG 5L).

A 2-mm cement mantle is desirable.

Care must be taken not to leave large areas of the liner uncovered.

<td>The patient must be compliant.</td>
</tr>
</tbody>
</table>
**Intraoperative bone assessment**
- The remaining acetabulum must be assessed for ability to support an uncemented socket. If partial inherent stability is not possible, then an antiprotrusio cage should be used.

**Bone preparation**
- Minimal additional bone should be removed.
- The cage should be supported by adequate superior and posterior bone, which may require augmentation to achieve.

**Cage fixation**
- The ischial flange may be fixed on or in the ischium.
- The socket portion of the cage must be fully seated.
- The ilial flange must be contoured to the ilium.
- Screws should be passed through the dome and ilial flange.
- Care should be taken to remain within the “safe zones.”

**POSTOPERATIVE CARE**
- Radiographs are taken to confirm appropriate cage positioning (**FIG 3**). Intraoperative radiographs may be beneficial to confirm cage positioning prior to final fixation of the device.
- The patient is allowed protected weight bearing as tolerated if bone augmentation was not necessary.
- The patient is restricted to toe-touch weight bearing for 6 to 12 weeks if bone augmentation was necessary. He or she is then allowed to increase weight bearing progressively on a schedule that is individualized to each patient.

**OUTCOMES**
- The survivorship of antiprotrusio cages has been acceptable in short- to mid-term follow-up.
- However, because most of these devices cannot achieve biologic fixation, it is assumed that they will loosen over time, although one series reported 92% survivorship at 21 years.4
- Other series have shown 100% survivorship at 7.3 years5 and 93.4% survivorship at 10.9 years.2
- The success of these devices also will depend on the environment in which they are placed.
- Most surgeons in North America are selectively using these devices in cases of severe acetabular deficiency in which a press-fit uncemented socket is not appropriate. This may predispose these devices to failure.
- A recent report on the use of the cage in the setting of discontinuity revealed a 31% revision rate at 46 months.1

**COMPLICATIONS**
- The use of antiprotrusio cages is accompanied by the complications inherent to significant revision surgery:
  - Blood loss
  - Infection
  - Neurovascular injury
  - Construct failure
  - Anesthetic and medical complications

Resection Arthroplasty and Spacer Insertion

Mark J. Spangehl and Christopher P. Beauchamp

DEFINITION
- Resection arthroplasty and insertion of a spacer is used for the management of chronic deep periprosthetic infection of the hip.
- The discussion in this chapter pertains to the diagnosis and management of late chronic infection. Acute infection, described below, has a different presentation, methods of diagnosis, and management algorithm.
- Antibiotic-loaded spacers are an adjuvant treatment for the management of deep infection by providing elusion of antibiotics into the local tissues.³
  - Historically, deep periprosthetic infection was treated by resection arthroplasty alone.
  - Depending on the type used, however, spacers allow for improved function between resection and reimplantation when compared with resection arthroplasty alone by providing soft tissue tension and an articulating surface and in most cases allowing weight bearing through the lower extremity.
  - Spacers can be grouped into articulating spacers or nonarticulating (static) spacers.
    - Articulating spacers can resemble either a total hip replacement, with antibiotic-loaded implants inserted on both the acetabular and femoral sides, or a hemiarthroplasty spacer, with an antibiotic-loaded implant inserted only on the femoral side.
    - Static spacers are blocks and dowels of antibiotic-loaded cement placed into the acetabulum and femoral canal after removal of the implants.

ANATOMY
- The pertinent anatomy of the hip is shown in FIGURE 1.
- The fasciae latae cover the musculature of the hip.
- Distally the fibers condense and form the iliotibial band, which inserts onto the lateral aspect of the proximal tibia (Gerdy’s tubercle).
- Proximally the fascia splits and envelops the gluteus maximus (inferior gluteal nerve) and the tensor fascia lata (superior gluteal nerve).
- Deep to the fascia lata, over the lateral aspect of the hip are the major abductors: the gluteus medius and minimus (superior gluteal nerve).
- More posteriorly, deep to the gluteus maximus, are the short external rotators.
  - From proximal to distal: piriformis (branches from S1 and S2), superior gemellus (nerve to obturator internus), obturator internus (nerve to obturator internus), inferior gemellus (nerve to quadratus femoris); slightly deeper is the obturator externus (posterior branch obturator nerve); distally is the quadratus femoris (nerve to quadratus femoris).
  - The sciatic nerve usually emerges from the lower border of the piriformis and is posterior to the short external rotators.
  - When approaching the hip posteriorly, retracting the short rotators posteriorly will provide some protection to the sciatic nerve.

- An ascending branch from the medial femoral circumflex courses over the posterior aspect of the quadratus femoris; this may produce bleeding during dissection.
- Anterior to the hip capsule is the iliopsoas tendon on which the femoral nerve lies as it crosses under the ilioinguinal ligament and enters the thigh.
- Retractors placed over the anterior wall need to be placed directly on bone to avoid injury to the nerve.

PATHOGENESIS
- Periprosthetic infections are classified as acute or chronic infections (Table 1).⁶,⁸,⁲⁴
- Acute infections are either acute postoperative infections or acute hematogenous infections.
  - If diagnosed early, acute infections can be managed with débridement and irrigation with component retention.
  - Chronic infections generally present in a delayed manner, usually months or occasionally years after the index procedure. The infection has likely been present since the original procedure, but because of the low virulence of the infecting organism, classic signs of infection are lacking, and hip pain may be the only presenting symptoms.
  - Chronic infections also include a missed or delayed diagnosis of an acute infection. A missed or delayed diagnosis of an acute infection must now be treated as chronic and no longer managed as an acute infection.

NATURAL HISTORY
- Chronic periprosthetic infection will continue to cause pain and disability.
- The severity of symptoms depends on the virulence of the organism, the overall health or comorbidities of the patient, and the status of the implants and surrounding soft tissues.
- Low-virulence organisms (eg, coagulase-negative \textit{Staphylococcus}) may present with chronic pain, whereas more virulent organisms (eg, \textit{Staphylococcus aureus}) or hosts that are immunocompromised may present with more obvious signs of infection.
- Untreated patients are at risk for seeding other joint replacements. The incidence is unknown and likely depends on the virulence of the organism and the host’s medical comorbidities.
- Patients who have multiple medical comorbidities or are infected with more virulent organisms may be at greater risk for signs or symptoms of systemic infection and, subsequently, seeding of other joints by hematogenous spread.
- With time, chronic infection can cause bone loss and loosening of implants.
- In addition to increased pain from implant loosening, the osteolysis, which may be secondary to both infection and loose implants, can result in an increased risk of periprosthetic fracture.
PATIENT HISTORY AND PHYSICAL FINDINGS
- In most cases, a careful history will lead one to suspect a diagnosis of chronic infection.
- Often patients give a history of poor wound healing, with prolonged drainage, prolonged antibiotic use, or surgical débridement.
- These cases represent missed or failed treatment for acute postoperative infections. Similarly, missed acute hematogenous infections, which are now chronic infections, present with a history of sudden deterioration in hip function, without other obvious causes.
- Another subset of patients with chronic infection present only with pain. Often it has been present since the time of the initial hip replacement procedure.
- There may also be a history of poor wound healing or prolonged drainage.
- The pain is usually different in character than the preoperative activity-related arthritic pain. It may be more constant, present at rest, and a dull ache in character.

![Antomy of the lateral aspect of the hip joint.](FIG 1)

**Table 1**

| Classification of Deep Periprosthetic Infection (based on timing of presentation) |
|---------------------------------|---------------------------------|
| Type of Infection               | Timing of Presentation          | Treatment                          |
| Acute postoperative infection   | 1–3 weeks after index operation| Débridement and component retention|
| Acute hematogenous infection    | Sudden onset of pain in well-functioning joint | Débridement and component retention |
| Late chronic infection          | Low-grade chronic infection presenting >1 month after index operation (includes missed or delayed diagnosis of acute infection) | Removal and reimplantation of implant |

- The physical examination is often nonspecific in the setting of chronic infection.
- The examination findings range from nearly normal, with only mild pain with range of motion, to more obvious signs of infection, such as a chronically draining sinus.
- Examinations to perform include the following:
  - Observe gait pattern. Pain or muscle weakness may cause limp. Trunk may shift over affected hip.
  - Trendelenburg sign. A positive result may indicate abductor dysfunction or pain or a neurologic problem (superior gluteal nerve or L5 nerve root).
  - Inspect any old incision sites and surrounding skin. Plan to incorporate all or as much of the old incisions as possible. A draining sinus generally indicates a deep infection.
  - Examine the soft tissue for thickness and compliance. Poor tissue integrity may require rotation flap for closure.
  - Passive range of motion. Significant stiffness may make surgical exposure more difficult. Excessive motion may increase the risk of instability.
  - Straight-leg raising may be limited by pain from infection or loose implants.
  - Assess true and apparent leg lengths.
  - Perform a neurovascular examination. Check and document status of motor group function, sensation, and pulses preoperatively in case of any change following surgery.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**
- Radiographs
  - In most cases, radiographs do not show signs of chronic infection. Radiographs are necessary to exclude other causes of aseptic failure and for surgical planning.
  - In a few cases, radiographs from patients with longstanding chronic infection will show signs of deep infection. A periosteal reaction is considered pathognomonic for deep infection. Sinus tracks, extending through bone, may rarely be seen (FIG 2).
Laboratory investigations
- The most useful laboratory tests, both to confirm and to exclude a suspected diagnosis of deep infection, are the erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP).
  - Various values have been considered positive (indicative of infection). It is generally accepted that an ESR above 30 mm/hr and a CRP above 10 mg/L are indicators of potential infection, provided the patient does not have other diagnoses that lead to elevated inflammatory markers.21
  - The sensitivity of the ESR or CRP, used individually, is diminished in the setting of nonvirulent chronic indolent infections.18 When used in combination, however, if both values are strongly negative (low normal) it is unlikely that the patient is infected, and other diagnoses should be considered.
- White blood cell count is rarely abnormal in chronic infection and is not helpful for diagnosing deep infection.
- Hip aspiration for culture and cell count is indicated if there is any clinical suspicion of infection, or if there is elevation of either the ESR or CRP. Any antibiotics that the patient may be receiving should be discontinued at least 2 to 3 weeks before aspiration to reduce the risk of false-negative cultures.1
  - The specimen should be separated into two, or preferably three, specimens for culture. If all cultures are positive for the same organism and the results correlate with the clinical presentation and elevation of inflammatory markers, then the diagnosis is confirmed.
- The aspiration is routinely sent for aerobic and anaerobic cultures. In patients who have been previously investigated, or managed for presumed infection with negative cultures, or in patients who are immunosuppressed (eg, transplant patients, HIV-positive patients, cancer patients undergoing chemotherapy), the specimen is also sent for fungal and mycobacterial cultures.
- Synovial cell count has become a useful investigation to help diagnose deep infection. Although currently values that are suggestive of infection are based on knee aspiration, it is likely that these values would hold true for infected hip replacements as well. A synovial white cell count of greater than 2000 cells/mL or over 65% polymorphonuclear leukocytes is suggestive of infection.12,23
- Frozen section is a helpful intraoperative test, but as with other investigations it must be interpreted within the context of the clinical presentation and the results of other investigations: no single test is 100% reliable. The sensitivity and specificity of frozen section are approximately 0.80 and 0.90, respectively.19
  - Tissue for frozen section should be obtained from the areas that look most inflamed. A positive result, indicative of infection, is considered when there are more than 5 polymorphonuclear leukocytes per high-power field.15
- Intraoperative Gram stain should not be used to determine the presence or absence of infection. In late chronic infection it has an extremely poor sensitivity.20

DIFFERENTIAL DIAGNOSIS
- Intrinsic
  - Aseptic loosening
  - Fibrous ingrowth (uncemented implants)
  - Polyethylene wear with synovitis
  - Modulus mismatch
  - Tendinitis (eg, psoas tendon impingement)
  - Bursitis or abductor avulsion
  - Heterotopic ossification
  - Stress fracture
- Extrinsic
  - Spinal pathology (eg, L2 nerve root impingement)
  - Vascular claudication
  - Hernia
  - Lateral femoral cutaneous nerve impingement

NONOPERATIVE MANAGEMENT
- In established cases of chronic infection, nonoperative management is rarely indicated for definitive treatment.
- Once the organism has been identified, antibiotic suppressive therapy may be used as a temporizing measure.
- Antibiotic treatment may be able to suppress the infection and will likely prevent bacteremia if surgical treatment has to be delayed.
- Antibiotic suppression may be considered in patients with very limited life expectancy, who have a reasonably well-functioning joint, provided that the infecting organism has been identified and the infection can be suppressed with a well-tolerated oral antibiotic.
- The use of antibiotics alone will not eradicate an established chronic infection, and they should not be used if curing the infection is the goal.

SURGICAL MANAGEMENT
- The favored method of management of chronic periprosthetic hip infection is a two-stage exchange: removal of all implants and foreign material, followed by delayed implantation.
- The time between stages allows the surgeon to observe the patient’s response to therapy, thereby allowing him or her to assess for the possibility of recurrence of infection after the antibiotics have been stopped and before implantation.
- The principles of surgical management during the first stage are removal of the implants and all foreign material, thorough débridement of the joint, and insertion of a high-dose antibiotic cement spacer (either articulating or static).
The patient is then treated with the appropriate antibiotic therapy, in addition to medical and nutritional management. This is ideally followed by period of time off all antibiotics to ensure clinical resolution of infection, after which the second-stage reimplantation is performed.

The principles of reconstruction during the second stage are as for aseptic revisions and independent of the infection.

If infection is suspected at the time of reimplantation, definitive reconstruction should not be performed and the patient should instead be treated with repeat débridement and insertion of a spacer.

Otherwise, if the prereimplantation workup is negative and if there is no suspicion of infection at the time of reimplantation, it is assumed that the patient is free of infection, and reconstruction should be performed in a manner that is likely to give the best long-term functional outcome.

In most cases, an uncemented reconstruction is favored.4,5,14,16,22 The use of cement is not specifically indicated for the second stage of reconstruction when a two-stage approach is used.

A variety of techniques have been described to create spacers after removal of the implants.4,5,9,13,25 The common principle involves using high-dose antibiotics in the bone cement to obtain high local concentrations such that the spacer does not act as a foreign body.

Prefabricated commercially available spacers currently contain only low doses (generally considered prophylactic levels) of antibiotics. The efficacy of these commercially available spacers has not been established. Currently we recommend against the use of these spacers and instead favor making spacers intraoperatively with high-dose antibiotics.

We use the Prostalac molds,2 which are described later. The technique can be adapted to other mold systems, however.

**Preoperative Planning**

Preoperative planning is as for any revision hip replacement procedure. Planning the steps used for managing the infection and inserting an antibiotic spacer is also required.

These steps include ensuring that the patient is medically stable to undergo the procedure, having the appropriate equipment available to remove the implants (eg, high-speed burrs, thin blade saws, ultrasonic cement removal equipment, trephines, acetabular removal systems) and having the equipment for making the antibiotic-loaded spacer intraoperatively.

Management of a chronically infected total hip replacement requires that every reasonable attempt be made to identify the organism preoperatively.

Although in most cases the antibiotics used in the bone cement will be the same, occasionally an atypical organism will be identified preoperatively, requiring alteration in the content of antibiotics mixed into the bone cement.

It is unlikely that nonimmunosuppressed patients with late chronic infections will become bacteremic if antibiotics are stopped for a short period of time. Therefore, antibiotics that the patient may be receiving preoperatively should be discontinued about 2 weeks before surgery to improve the yield of positive cultures at the time of surgery.

Occasionally, a second organism or an organism with a different antibiotic sensitivity profile than that obtained preoperatively will be identified from intraoperative cultures. If the patient complains of increasing pain or becomes febrile, however, the antibiotics should be resumed to prevent systemic sepsis.

The appropriate molds and antibiotics should be mixed into the cement need to be available for making the spacer intraoperatively.

The most commonly used antibiotics are vancomycin and gentamicin or tobramycin. Other antibiotics can be used as well (Tables 2 and 3).

Intrapelvic cement, if present, needs to be identified preoperatively.

Small amounts can be removed from the defect within the floor of the acetabulum.

Large amounts of cement require a preoperative contrast CT scan to assess the location of cement relative to intrapelvic structures. A separate retroperitoneal approach may be required and should be planned.

Radiolucent bone cement also requires CT evaluation preoperatively, to determine its distal extent within the femoral canal or within the pelvis.

Positioning

- Patients are positioned as for other revision hip procedures.
- The lateral decubitus position, with the affected hip upward, is favored. The extremity is free draped with sufficient exposure of skin to allow for extension of the incision as required.
- If a retroperitoneal approach is required for removal of medial cement, the patient is positioned supine for this portion of the procedure.

Approach

- The approach depends on the fixation status of the implants, length of the cement column if present, quality of bone, and stiffness of the hip joint.
- The primary goals of the exposure are to allow for safe, efficient, and thorough removal of the implants and cement or other foreign material, and to allow for thorough débridement of the joint.
- An extended trochanteric osteotomy is usually used. This provides for excellent exposure of the acetabulum and allows for safe removal of the femoral component.
- If the femoral component is loose or has minimal proximal fixation, a standard approach can be used. Radiographs must be carefully inspected to ensure that removal of the femoral component can be accomplished from above.
- Varus remodeling of the proximal femur, or cement that is wider distally than proximally and still well fixed to the implant within the canal, impedes removal of the femoral component and increases the risk of fracture (FIG 3).
- A posterior approach is favored as this approach is more extensile and still allows for an osteotomy should removal of implants become more difficult than expected.
- The skin incision should be made through the previous incision, unless the old incision significantly compromises exposure of deep structures. A portion of the old incision can usually be incorporated; however, when joining the old incision, avoid acute angles to reduce the risk of wound edge necrosis.
- The old incision can be excised to give fresh, nonscarred skin edges that may improve wound healing.
- Sinus tracts should be excised as an ellipse.
- Once the joint has been exposed, at least three samples are obtained for culture.
- Removal of the implants is then carried out as per techniques of nonseptic revision cases and will not be detailed here (please see corresponding chapters).
- Removal of implants and débridement is more thorough than in aseptic revisions, however, and every attempt should be made to remove all foreign and potentially infected material.
- The presence of intrapelvic cement may require a separate retroperitoneal exposure if the cement cannot be gently removed through the medial defect within the floor of the acetabulum.

FIG 3 • AP radiograph of loose femoral component. The stem has failed at the bone–cement interface and the cement is still well fixed to the implant. Removal from above would be difficult as the cement becomes wider in the metaphyseal region (white arrows). An extended trochanteric osteotomy is required to remove the stem safely.

ARTICULATING ANTIBIOTIC SPACER

- After exposure and removal of the implants, the joint is thoroughly débrided. It is important to remove all foreign material, which is potentially infected.
- Retention of cement or other foreign material is associated with an increased failure rate for curing the infection.
- Intraoperative radiographs can be used to look for retained cement. An arthroscope passed down the femoral canal can also be used to inspect the canal for remaining cement.
- The steps to using a system of molds to make an articulating spacer and to maximize efficiency are as follows:
  - Remove infected femoral component (and cement if applicable).
  - Size and make the antibiotic-loaded femoral implant in the appropriate mold.
  - While the cement for the femoral component is hardening in the mold, remove and débride the acetabulum.
- Cement the acetabular component into the acetabulum with antibiotic-loaded cement.
- Remove the femoral component from the mold and insert into the femoral canal.
- Perform trial reduction.
- If the femoral component is not stable within the femoral canal and if there is obvious rotation or risk of significant subsidence, a third batch of antibiotic-loaded cement is mixed. When doughy, the cement is packed anterior and posterior to the femoral implant to provide rotational and axial stability.
- Reduce the hip and close.

**Spacer Creation**

- For most infections, including methicillin-resistant organisms, the antibiotic mixture used in the cement is 3.6 g of gentamicin or tobramycin, 3 g of vancomycin, and 2 g of cefazolin per pack (40 g) of cement. Palacos is favored, as most studies have indicated superior elution compared with other cements.\(^7\)
- Most cases require a total of two mixes of cement (one for the acetabulum and one for the femoral mold). If more than two batches are required and the patient is renally impaired (serum creatinine above 1.5 mg/dL), the dose is decreased to 2.4 g of gentamicin (or tobramycin), 2 g of vancomycin, and 2 g of cefazolin per batch of cement.
- The Prostalac molds are available in variety of sizes and lengths (120, 150, 200, and 240 mm). The length of implant to be made depends on the length of the extended trochanteric osteotomy that is usually required for exposure, the amount of bone loss, and the size of the canal.
- In most cases a middle (200 mm) or long (240 mm) stem is chosen as a longer length also helps achieve better rotational and axial stability within the canal.
- Antibiotics are mixed with one batch of cement in a mixing bowl and then placed into the mold.
- The mold is closed but not fully tightened (to allow for cement to extrude), and the stem is inserted. The mold is then fully tightened and extruded cement is removed from its outer aspect (TECH FIG 1).
- Alternatively, after filling the open mold with cement, the implant is laid into the mold, which is closed over the implant.

**Implant Placement**

- While the cement is hardening in the femoral mold, the infected acetabular component is removed and the socket débrided. Acetabular reamers can be used to help with débridement, but excessive bone loss from reaming should be avoided.
- A second mix of antibiotic-loaded cement is prepared, and, when it is doughy, the polyethylene acetabular implant is cemented into the socket.
- A “perfect cement technique” should be avoided, since this can make removal, at the time of reimplantation, more difficult.
- Waiting until the cement is doughy and applying some but not excessive force when cementing in the liner will provide a stable cup that can be readily removed.

TECH FIG 1 • A. The femoral component is inserted into the mold, which has been filled, before closing, with antibiotic-loaded cement. B. The femoral component is being removed from the mold. The extruded cement seen on the implant medially and laterally can be removed with a ronguer.

- If there are large acetabular defects, extra cement removed from the femoral mold can be shaped over a reamer of approximate size to make an “antiprotrusio-like” cup that can be placed into the floor of the acetabulum before cementing in the polyethylene cup (TECH FIG 2A).
- Warm saline can be poured into the acetabulum to decrease the setting time.
- Once the acetabular cement has hardened, the femoral component is removed from the mold (see Tech Fig 1B) and inserted into the femoral canal.
- In many cases, the stem is press-fitted into the canal, and good rotational and axial stability is obtained and no further adjustment is required.
- In some cases, the fit may be too tight and the antibiotic-loaded implant will not fully seat to the desired level.
- A high-speed burr is used to remove high points or areas of impingement to allow the stem to seat at the desired level.
- In other cases, especially with significant bone loss or very large canals, the femoral component is loose within the femoral canal.
- A trial reduction is performed to estimate leg lengths, and the desired position of the stem within the femoral canal is noted.
The hip is again dislocated and the stem is placed at the desired position. A third batch of antibiotic-loaded cement is mixed and when in a doughy consistency, cement is packed anterior and posterior to the implant to provide rotational and axial stability (TECH FIG 2B–D).

Once the stem is stable within the femoral canal, a trial reduction can be performed to assess leg lengths and stability.

The appropriate femoral head is then placed onto the stem and the hip is reduced and closed.

The Prostalac articulating antibiotic spacer uses a snap-fit all-polyethylene acetabular implant into which the femoral head is snap-fitted into the cup when reduced, enhancing hip stability (TECH FIG 2E).

The snap-fit poly liner may reduce the risk of dislocation, particularly in situations of proximal femoral bony or soft tissue deficiency.

The initial steps for using a nonarticulating spacer are as for the articulating spacer.

This involves ensuring that all the foreign material is removed and the hip is thoroughly débrided.

The same antibiotic concentrations are used in the bone cement.

For an unusual organism, the antibiotics can be adjusted to be organism-specific, but for most infections, the mixture is outlined above.

Two mixes of antibiotic-containing bone cement are required: one for the acetabulum and one for the femur.

Once the hip is débrided, one mix of antibiotic-loaded cement, in a partially polymerized doughy consistency, is placed into the socket. It is gently molded into the acetabulum, matching the bony contour to give some stability to the cement block, to prevent it from migrating or dislodging spontaneously.

The second mix is made into a tapered dowel. Once hardened, the dowel is placed down the femoral canal.

It is important to make a taper, so as to be able to easily extract the dowel at the time of reimplantation.

The nozzle from a cement gun can be used to make a long tapered dowel (TECH FIG 3).

An alternative method is to wrap cement around a threaded pin, again making sure that a taper is created with cement larger proximally to keep the dowel from migrating down the canal.

Once the spacers are inserted, the hip is closed.
TECH FIG 3 • A. A nonarticulating static spacer can be made from the nozzle of a cement gun. The nozzle provides a gentle taper and a larger area of cement proximally to prevent the cement dowel from migrating down the femoral canal. B. AP radiograph of a nonarticulating static spacer. Note the antibiotic-loaded cement block within the acetabulum and the cement around the Steinmann pin within the femoral canal.

PEARLS AND PITFALLS

Cementing polyethylene liner for articulating spacer
- Avoid overly aggressive pressurization, which can make removal more difficult.
- Apply modest insertion pressure to the poly cup with partially polymerized doughy cement.

Large medial acetabular defect
- To avoid intrapelvic cement from a large medial defect, an “antiprotrusio” cement block can be made by shaping cement over an appropriate-sized reamer. Place into acetabulum, covering the defect before cementing poly cup in place.

Femoral stem that is rotationally unstable
- Femoral implant may be rotationally or axially unstable in very large canals. Mix additional antibiotic-loaded cement, and when it is partially polymerized and doughy, pack it around the proximal portion of the implant to make it rotationally and axially stable.

Severe proximal femoral bone loss
- With severely deficient or absent proximal femoral bone, place the implant at the desired position during trial reduction. After redislocation, position the implant at the noted position, and place a mix of antibiotic-loaded cement that is partially polymerized and doughy at the implant–host bone interface. Overlap cement onto host bone to make the implant rotationally and axially stable (FIG 4).

Femoral dowel for nonarticulating spacer
- The nozzle of a cement gun has a slight taper that allows it to be used as a mold for a femoral dowel.

Mixing antibiotics into cement
- When mixing high-volume antibiotics into cement, depending on which antibiotics are used (eg, Nebcin [tobramycin], which is a very high-volume powder), the handling properties can become difficult because of poor viscosity. The cement has a very dry, powdery feel, making it difficult to handle.
- To improve the handling properties, two techniques are helpful:
  - Add a few extra milliliters of monomer liquid from an extra package of cement.
  - Mix slightly cooled monomer and polymer together. When well mixed but still in a very liquid phase, add the antibiotic powder to the mixed cement.

FIG 4 • An example of severe proximal femoral bone loss with deep infection. A. Preoperative radiograph showing severe proximal bone loss with infected bone. B. Postoperative articulating spacer radiograph. The femoral component is placed at the desired level and an extra mix of antibiotic-loaded cement is placed at the bone–implant junction to provide rotational and axial stability.
POSTOPERATIVE CARE
Management of the Infection
- Infection management consists of medical support, nutritional support, and the appropriate antibiotics to treat the infecting organism(s).
- The optimal duration and route of antibiotics remain controversial.
  - Most authors recommend 6 weeks of intravenous antibiotic therapy, although there is considerable variability in published reports, ranging from 0 to 9 weeks of intravenous antibiotics and none to more than 2 years of oral antibiotics.
  - The choice of antibiotics depends on the organism, but there is a tendency, such as with methicillin-resistant staphylococcal infections, to use multiple antibiotics for synergistic effect (eg, vancomycin and rifampin).10
- We favor 6 weeks of antibiotics, at which time the antibiotics are discontinued. Inflammatory markers (ESR and CRP) are followed and repeated at 6 weeks (at the time the antibiotics are stopped). The inflammatory markers have often returned to normal and reimplantation is planned for around 3 months from insertion of the spacer, provided that the inflammatory markers remain normal prior to reimplantation.
- If the ESR and CRP remain elevated at 6 weeks, however, we still favor stopping the antibiotics and following the patient’s course clinically.
  - The ESR and CPR are repeated at 4-week intervals. If they return to normal or have markedly decreased from very high levels preoperatively to near-normal, and there are no clinical signs of ongoing infection, then reimplantation can be planned for 3 to 4 months after insertion of the spacer.
- If the inflammatory markers remain elevated at 3 months, the options are as follows:
  - Continue to follow the patient clinically, particularly if he or she is functioning well with an articulating spacer, and reinvestigate prior to the planned reimplantation with repeat ESR and CRP, as well as a hip aspiration for cell count.
  - Repeat the debridement and insertion of a new antibiotic spacer.
- Multiple debridements at short intervals, based solely on elevated inflammatory markers, should be avoided.
- Routine reaspiration for culture is of limited value, as periarticular antibiotic levels are often still above minimum inhibitory concentrations at 3 months. Synovial white cell count differential may be of greater value, but data to recommend this routinely are limited.

Management of the Hip (Spacer)
- Postoperative weight bearing and mobility depend on the type of spacer used.
  - Most patients with an articulating spacer are very functional between stages, often having minimal pain and ultimately ambulating near full weight bearing with a cane or walker prior to reimplantation.
  - Patients with articulating antibiotic spacers that have a stable press fit, with good rotational stability, are allowed to mobilize touch to light partial weight bearing for 6 weeks, followed by 50% weight bearing for 4 to 6 weeks.
  - If follow-up radiographs show no significant change in implant position and the patient is functioning well with minimal symptoms, full weight bearing as tolerated is allowed until the time of reimplantation.
- If there is concern about the stability of the femoral component within the femoral canal (eg, large canal with difficulties getting good rotational or axial stability of the implant in the canal), then the patient is maintained at 50% weight bearing until the time of reimplantation.
- If a nonarticulating spacer is used, then patients generally cannot bear weight through the lower extremity and are kept touch weight bearing until reimplantation.

OUTCOMES
- The overall success for curing periprosthetic hip infection using a two-stage exchange technique is approximately 90% to 93%.4,5,7,8,14,25,26
- Numerous variables influence the success of treatment:
  - Depth of infection
  - Time from index operation
  - Prosthetic status (fixation and position)
  - Soft tissue status
  - Host status (medical comorbidities)
  - Pathogen (virulence)
  - Surgeon capabilities
  - Patient expectations
- Without the use of antibiotic-loaded cement spacers and without antibiotic-loaded cement at the time of reimplantation, the cure rate for infection using two-stage (delayed) reconstruction is approximately 82%.7
- This cure rate is also similar to a one-stage (direct) exchange in which antibiotic-loaded cement is used at the time of the direct exchange. This implies that delayed reconstruction and the use of antibiotic-loaded spacers are in part responsible for the improved success rate when treating infected total hip replacements.
- Combining series of patients treated with a two-stage (delayed) reconstruction without antibiotic spacers, but with antibiotic-loaded cement at the time of reimplantation, reveals a success rate of approximately 90%.7
- Patients treated with a two-stage (delayed) reconstruction using antibiotic-loaded spacers and uncemented reconstruction show a similar success rate to those treated with spacers and antibiotic-loaded cement at the time of reconstruction. This success rate is approximately 90% to 93%.7,8,25,26
- Uncemented reconstruction at the time of reimplantation, when used with antibiotic-loaded spacers, has not resulted in a lower infection cure rate.5,7,14 Also, uncemented reconstruction will likely result in a better long-term mechanical survival.
- Using the articulating Prostalac antibiotic-loaded spacer has an infection cure rate of 93% (45/48 patients).26 In this series of patients, three became reinfected—two with new organisms and one with the same organism.
- The use of the articulating spacer allows patients to be more functional and thereby reduces the urgency to proceed with reimplantation. This delay between resection and reimplantation allows the surgeon to monitor the patient and assess for possible recurrence after the antibiotics have been stopped.
- The optimal time from resection to reimplantation remains controversial; however, the longer the patient remains clinically free of infection between insertion of the spacer and reimplantation, the more likely one has cured the infection.
COMPlications

- General medical complications are similar to other revision procedures (eg, thromboembolic disease, postoperative ileus, cardiac ischemia) and will not be further detailed.
- Local complications can occur with removal of the implants or with the spacer.
- Removal of the implants, particularly well-fixed implants (as in other revision procedures), can result in bone loss, fracture, or canal perforation. These complications are not reported to be any greater in septic versus aseptic revisions.
- Complications related to the spacer depend on the type of spacer used.
- Static spacers, in addition to functional problems experienced by the patient, can result in difficulties at the time of reimplantation because of contractures or excessive shortening. Excessive shortening may make re-establishment of leg lengths more difficult.
- Articulating spacers may cause polishing or sclerosis of the endosteum, resulting in bone that is less suitable for cementing should a cemented reconstruction be chosen at the time of reimplantation. However, cementless reconstruction is widely used and is not associated with an increased risk of infection. Cementless reimplantation will likely result in better long-term prosthetic fixation, particularly in younger or more active patients. We rarely use cemented femoral reimplantation at the time of reimplantation and reserve its use for very low-demand patients with limited life expectancy.
- Articulating spacers, as with conventional hip replacements, can lead to hip instability. This may be more common if there is bony or soft tissue deficiency. A snap-fit polyethylene liner is routinely used in the Prostalac system and markedly reduces this problem.
- Complications of the infection are failure to cure the infection and side effects or toxicity related to antibiotic use. Although there is some variation in the literature, one can generally conclude that the results for curing the infection are about 90% to 93%.4,5,7,8,14,25,26
- The ability to cure the infection relates to a number of factors: the status of the local soft tissues, systemic comorbidities, the virulence of the organism, and surgical technique.
- The surgeon can improve outcomes by identifying the organism, performing a thorough débridement, and using the appropriate high-dose antibiotics in the spacer. As noted above, the dose of antibiotics in cement may require adjustment in patients with renal insufficiency. Proper medical and nutritional support may also improve the outcome. Depending on which systemic antibiotics are used, monitoring serum levels is required to avoid toxicity.

REFERENCES

**DEFINITION**

- **Hip reimplantation** refers to the insertion of another prosthesis after removal of the original, infected prosthesis. It may be single- or two-staged, cemented or uncemented.

**ANATOMY**

- The posterolateral approach is the most versatile approach in hip reimplantation surgery. Extended trochanteric osteotomy (ETO) occasionally may be required.
- The sciatic nerve is the major nerve most commonly at risk during the posterolateral approach to the hip. In patients with severe scarring, it may be necessary to expose the nerve as it emerges deep and inferior to the piriformis muscle and superficial to the obturator internus muscle.
- In a direct lateral (ie, transgluteal) approach, function of the abductors may be compromised if sufficient care is not taken to avoid injury to the superior gluteal nerve, located 5 cm proximal to the greater trochanter.
- The selection of prostheses for both femoral and acetabular reconstruction is determined by a number of factors, primarily including femoral and acetabular bone defects, quality and quantity of remaining host bone for osseointegration or cementation, status of the soft tissues and abductors, and surgeon preference.
- For acetabular reconstruction, screw fixation often is necessary. The safest zone for insertion of acetabular screws is the posterior superior quadrant.

**PATHOGENESIS**

- Prosthetic reimplantation usually is performed following resection arthroplasty or first-stage revision arthroplasty for infection. It is essential to ensure a sterile surgical field prior to hip reimplantation surgery, as discussed later in this chapter.
- Usually this requires the patient to demonstrate normal values for erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), and hip aspiration for culture. Occasionally, test results may be equivocal, in which case nuclear medicine imaging is required to confirm absence of infection.
- The organisms most commonly isolated in infected total hip replacements are *Staphylococcus aureus*, *Staphylococcus epidermidis*, and gram-negative bacteria, with increasing prevalence of antibiotic-resistant bacteria.

**NATURAL HISTORY**

- Eradication of infection is key to the success of hip reimplantation surgery, regardless of the method of hip reconstruction.
- Persistent or recalcitrant infection, suggested by raised CRP and ESR values and confirmed by tissue or fluid culture (aspiration or biopsy), is a contraindication to reimplantation surgery.
- The options in such a scenario are to continue with antibiotics, repeat the first-stage procedure, or perform resection arthroplasty.

**PATIENT HISTORY AND PHYSICAL FINDINGS**

- The main presenting symptom of patients with a periprosthetic infection is pain, particularly constant pain while the patient is at rest.
- Delayed wound healing, persistent wound drainage, and a history of superficial wound infection after the primary procedure are highly suggestive of infection.
- Risk factors for infection include history of diabetes mellitus, chronic skin lesions, the use of corticosteroids, and any type of immunocompromise.
- Initial assessment should begin with a general medical examination.
  - The hip wound is examined for warmth, erythema, fluctuance, discharging sinuses, and the presence of any hematoma.
  - An erythematous, warm wound with draining sinuses indicates persistent, ongoing infection.
  - Defects in the underlying fascia often are palpable, and may indicate a higher risk of wound dehiscence postoperatively.
  - The abductors should be palpated and their function assessed.
  - Full neurologic examination and palpation of pulses are performed.
  - Preoperative weakness of leg extensors or a partial foot drop may indicate scarring around the sciatic nerve.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Infection is excluded by serial assessment of the ESR (normal <30 mm/hr) and CRP (normal <10 mg/mL).
- ESR and CRP may be elevated if the patient has other inflammatory systemic diseases (eg, rheumatic disease) and therefore may not be completely reliable in such cases.
- Preoperative hip aspiration, culture or biopsy, and sensitivity may be necessary if the ESR and CRP remain elevated. Antibiotics should be stopped for a minimum of 2 weeks before aspiration to avoid false-negative results.
- Three samples are obtained at the time of hip aspiration, including a tissue sample if feasible. A positive result is considered to be one in which growth is obtained in two separate specimens.
- Radiographs are obtained, including an anteroposterior (AP) view of the pelvis, lateral view of the hip, and Judet views, if necessary, to assess integrity of acetabular columns. In some cases, AP and lateral views of the full length of the femur may be necessary. Bone defects should be estimated on plain radiographs and appropriate reconstructive prostheses made available.
- CT scans occasionally are helpful to ascertain the magnitude of acetabular bone defects.
- Radiographs should be used together with the physical examination to estimate appropriate techniques for leg length restoration or for restoration of hip stability.
The abductors be inadequate, and to minimize risk to neurovascular structures.

**SURGICAL MANAGEMENT**
- The aims of surgical treatment are to eradicate infection, minimize morbidity, and restore function.
- Typically, the hip is flail, but it may contain an antibiotic-loaded spacer. The goal is to remove any temporary spacer and implant a permanent hip replacement prosthesis.

**Preoperative Planning**
- It is important to anticipate the need for specialized implants and instruments before surgery.
- Careful preoperative templating is essential to anticipate implant size, length, and offset (**FIG 2**).
- The template is used to restore leg lengths, medial hip offset, and hip center of rotation.
- Insufficiency of hip abductors may require constrained acetabular implants or large-diameter femoral head components.
- The microbiology laboratory should be informed of the possibility that intraoperative frozen section analysis may be required in equivocal cases of persistent infection.
- Alternative surgical plans are useful to have at hand in case of unexpected intraoperative findings or complications.

**Positioning**
- The patient is positioned in the lateral decubitus position with anterior and posterior supports (**FIG 3**).
- The pelvis must be vertical, and it must be confirmed that the supports are stable.
- Patient positioning must be performed under surgeon supervision, because errors in positioning may result in acetabular component malalignment.

**Approach**
- The surgical approach is chosen after careful preoperative consideration of important factors, including:
  - Previous approach
  - Anatomic location and extent of bone loss
  - Anticipated instability
  - Function of the abductors
  - Surgeon preference and training
- The main options are:
  - Direct lateral (transgluteal) approach
  - Posterolateral approach
  - Trochanteric osteotomy
  - Trochanteric slide osteotomy
  - ETO

**FIG 1** Preoperative radiographs.

C. Obturator oblique view. D. Iliac oblique view.

**FIG 2** Preoperative templating is essential to determine the diameter and length of the implant that may be needed.

**FIG 3** Patient positioned in the lateral decubitus position.
HIP EXPOSURE AND REMOVAL OF ANTIBIOTIC SPACERS

- The posterior approach can be used for surgical exposure.
- The sciatic nerve is identified and is protected throughout the procedure. This is facilitated by placement of the foot on a padded stand with the hip in internal rotation during exposure.
- The short external rotators and posterior capsule are identified and incised as a composite flap. These are tagged with sutures for later repair. The gluteus maximus tendon must be released in most cases due to severe scarring and the need to mobilize the femur.
- Samples are obtained from within the hip joint, for bacteriology.
- Intraoperative frozen sections are obtained if persistent infection is suspected.
- The hip is dislocated, with internal rotation of the femur.
- The femur is further mobilized by incising the anterior scar tissue that tethers it onto the acetabular bone. It may be necessary to release the anterior femoral capsule with cautery, with a femoral retractor placed anteriorly to expose the femoral canal (TECH FIG 1A).
- Removal of cement, soft tissue, and bone from the shoulder of the prosthesis and greater trochanter facilitates removal of the preexisting antibiotic implant spacer, and reduces the risk of greater trochanter fracture (TECH FIG 1B).
- A femoral extractor should be used to remove the femoral antibiotic spacer (TECH FIG 1C), ensuring complete removal of the antibiotic-loaded cement and implant (TECH FIG 1D).
- The acetabular antibiotic spacer is removed with a Cobb elevator, ensuring no further bone loss (TECH FIG 1E).
- Acetabular débridement is performed using a combination of curettes, rongeurs, and Cobb elevators to remove any residual necrotic tissue, ensuring complete exposure of the acetabulum (TECH FIG 1F).

**TECH FIG 1** • A. Incising the anterior femoral capsule with electrocautery to allow exposure of the proximal femur. B. Removal of bone and soft tissue from the collar of the femoral prosthesis. C. Femoral extractor facilitates safe removal of the femoral component. D. Complete removal of the antibiotic cement-coated femoral prosthesis is confirmed. E. Safe removal of the acetabular antibiotic spacer with a Cobb elevator. F. The acetabulum is fully exposed after complete débridement.
ACETABULAR REIMPLANTATION

- The acetabulum is reamed sequentially in 2-mm increments to obtain a concentric, hemispheric surface, taking care to preserve the rim of the acetabulum (TECH FIG 2A).
- Press-fit of an implant 1 to 2 mm larger than the last reamer is used.
- The implant is inserted in 40 degrees of lateral opening and 15 to 20 degrees of anteversion (TECH FIG 2B).
- It is ascertained that the component is uniformly in contact with the underlying host bone.
- Supplementary screw fixation is required in most cases.
- The appropriate trial liner is placed into the acetabulum, for later trial reduction after femoral canal preparation.

Two-Stage Reimplantation with Uncemented Extensively Porous-Coated Femoral Stem

- Femoral preparation may begin after a thorough débridement and after acetabular reconstruction. The length and diameter of the femoral canal are anticipated by careful preoperative templating.
- Femoral débridement is performed with reverse hooks, curettes and brushes, and pulsed lavage.
- The femoral canal is sequentially reamed, guided by preoperative templating, until cortical resistance is encountered over a length of at least 5 to 6 cm (TECH FIG 3A).
- Trial reduction is performed, ensuring satisfactory leg lengths, soft tissue tension, range of motion, and a stable hip (TECH FIG 3B).
- Under-reaming the femoral canal by 0.5 mm compared with the diameter of the actual femoral implant is confirmed by checking with a “hole gauge.”
- In an extensively porous-coated femoral component, 5 to 6 cm of diaphyseal fit (so-called “scratch fit”) is required to provide axial and rotational stability.
- The final implant is inserted into the femoral canal. It should be inserted to within 5 cm of its final position by hand, otherwise it should be reamed line to line to avoid inadvertent femoral fracture (TECH FIG 3C).
TWO-STAGE REIMPLANTATION WITH UNCEMENTED TAPERED FLUTED FEMORAL STEM

- Femoral preparation may begin after a thorough débridement and after acetabular reconstruction.
- Femoral débridement is performed with reverse hooks, curettes and brushes, and pulsatile lavage (TECH FIG 4A).
- Femoral canal reaming is performed with tapered reamers, with the depth and diameter guided by preoperative templating until endosteal contact is made (TECH FIG 4B).
- The aim of diaphyseal reaming is to ensure implant stability, which will resist stem subsidence.
- The length of the stem, as determined by preoperative templating, should be at least 2 cortical diameters distal to any potential stress risers, eg, the tip of an ETO.
- Unlike fully porous-coated cylindrical stems, underreaming the femoral canal by 0.5 mm compared with the diameter of the actual femoral implant is not recommended. Line-to-line reaming is preferred.
- Proximal femoral preparation is then performed using conical reamers.
- Trial reduction is performed for assessment of correct femoral stem anteversion, limb length, soft tissue tension, range of motion, and hip stability (TECH FIG 4C).
- The modularity of the uncemented tapered fluted femoral stem allows adjustment of femoral anteversion (TECH FIG 4D).
- Torsional and axial stability of the implanted prosthesis may be ensured by test torquing the femoral component.

PART 3  ADULT RECONSTRUCTION • SECTION I  HIP RECONSTRUCTION

POSTOPERATIVE CARE
- Postoperative care is individualized, depending on the complexity of the reimplantation procedure.
- The quality of implant fixation, severity of preoperative bone loss, hip stability, technical factors encountered during the operation, and patient compliance influence the amount of weight bearing permitted and restrictions on hip range of movement.
- If a transgluteal (direct lateral) approach was used, restriction of active abduction may be necessary.
- Clear postoperative instructions and frequent communication with the multidisciplinary team are essential. Instructions include postoperative blood work, deep venous thrombosis prophylaxis, and perioperative antibiotic requirements.

OUTCOMES
- An uncemented two-stage procedure may successfully eradicate infection in 92% to 93% of cases.4,5,7
- Single-staged reimplantation with the use of antibiotic-loaded cement has a success rate of 77% to 86%,1,10
- A two-reimplantation procedure with the use of antibiotic-containing bone cement in the reimplantation procedure attains a success rate of 90% to 95%.6,8
- A two-staged hip reimplantation is the procedure of choice in most cases.

COMPLICATIONS
- Recurrent infection after reimplantation is a devastating complication, and is associated with a poor outcome.9
- Recurrent infection may be either recurrence of the initial infection, which typically is due to failure of the reimplantation procedure, or a new infection by a different organism, which often is due to multiple patient risk factors and indicates host failure.7
- Hip dislocation, leg-length discrepancy, venous thromboembolism, nerve and vessel injury, fracture, and a small mortality risk are potential complications, as they are for any revision arthroplasty.

REFERENCES
DEFINITION

- According to the prefix peri (meaning “around”), a periacetabular osteotomy (PAO) is defined as an osteotomy that involves dislodging the hip socket from its bony bed in the pelvis without disturbing the normal pelvic anatomy. The socket is then reoriented in a more appropriate position, reducing the deleterious effects of some unfavorable conditions.
- Closure of the acetabular growth plate is a precondition.
- Although the purpose of all reconstructive pelvic osteotomies is the same, the PAO modifies only the orientation of the acetabulum.
- Ideally, the site of the periacetabular osteotomy should be as close to the acetabulum as needed to mobilize it, to preserve the blood supply, and to avoid joint penetration.
- By definition, PAOs include the spherical or rotational osteotomies described by Eppright, Nynomiya, and Wagner, the polygonal Bernese osteotomy as described by Ganz, and their modifications.
- The osteotomy described by Eppright is barrel-shaped and is oriented along an anteroposterior axis. This osteotomy allows for excellent lateral coverage, but only a limited amount of anterior coverage can be achieved.
- The Wagner type I osteotomy is a single, spherical osteotomy that provides simple rotatory displacement without lengthening, shortening, medialization, or lateralization. The relative disadvantage, which involves simple acetabular realignment, is that the intact medial buttress of the quadrilateral plate prevents medialization of the joint.
- The Wagner type II osteotomy is a spherical acetabular osteotomy that combines rotation of the isolated acetabular fragment with a lengthening effect. It is accomplished by placing an iliac bone graft in the cleft between the rotated acetabular fragment and the overlying ilium.
- The Wagner type III osteotomy is a spherical acetabular osteotomy that involves both acetabular realignment and medialization. It is achieved by the creation of the initial basic spherical acetabular osteotomy followed by an additional Chiari-like cut proximally. Fixation usually is obtained with a special construct of tension Kirschner wires connected by a semitubular plate.
- The Bernese osteotomy involves a series of straight cuts to separate the acetabulum from the pelvis. It is the preferred acetabular procedure at many centers for several reasons:
  - It can be done through one incision with a series of straight, relatively reproducible, extra-articular cuts.
  - It allows for large corrections of the osteotomized fragment in all directions that are needed, including lateral rotation, anterior rotation, medialization of the hip center, and version correction.
  - It is inherently stable, in part because the posterior column remains intact.

- Minimal internal fixation is required.
- Early ambulation with no external immobilization is possible.
- The vascularity of the acetabular fragment through the inferior gluteal artery is preserved.
- Arthroty can be done without risk of further devascularization of the osteotomized fragment.
- The shape of the true pelvis is not markedly changed, allowing women who become pregnant after the procedure to have normal vaginal delivery.
- It can be done without violation of the abductor mechanism, facilitating a relatively rapid recovery.

ANATOMY

- The basic anatomy around the hip consists of the superficial surface anatomy and deep bony, muscular, and neurovascular anatomy.
- The clinically relevant surface anatomy of the hip consists of several superficial bony prominences.
- The anterior landmarks consist of the prominent anterosuperior iliac spine and anterior inferior iliac spine, which serve as insertion points for the sartorius and direct head of the rectus femoris, respectively.
- The greater trochanter and the posterior superior iliac spine also are easily identified on the posterolateral aspect of the hip.
- The proximal femur and the acetabulum constitute a very stable and constrained bony articulation, which can be classified with regard to:
  - Histology: synovial (diarthrodial)
  - Morphology: enarthrodial (ball and socket)
  - Axes of movement: polyaxial
- The acetabulum is formed by the confluence of the ischium, ilium, and pubis, which usually are fused by 15 to 16 years of age.
- It is oriented approximately 45 degrees caudally and 15 degrees anteriorly. It is hemispherical in shape and covers 170 degrees of the femoral head.
- The articular surface is horseshoe-shaped and is lined with hyaline cartilage, except at the acetabular notch.
- The acetabular labrum is a fibrocartilaginous structure that runs circumferentially around the periphery of the acetabulum. It increases the depth of the bony acetabulum and contributes to its stability. It is attached to the acetabular articular cartilage via a thin transition zone of calcified cartilage on the articular side. The nonarticular side of the labrum is attached directly to bone. Only the peripheral one third or less of the labrum has a rich blood supply, provided by branches from the obturator, superior gluteal, and inferior gluteal arteries. Pain fibers are most concentrated anteromedially and anterosuperiorly.
The transverse acetabular ligament connects the anterior and posterior portions of the labrum.

The ligamentum teres originates from the transverse ligament over the acetabular notch and inserts into the fovea of the femoral head.

The proximal femur is formed by the femoral epiphysis and the trochanteric apophysis, both of which ossify by 16 to 18 years of age. The femoral head is approximately two thirds of a sphere and is covered with hyaline cartilage, except at the foveal notch.

The angle between the shaft and the neck is approximately 125 degrees, with 15 degrees of anteversion related to the posterior femoral condyles.

The joint capsule attaches to the margins of the acetabular lip as well as the transverse ligament and extends like a sleeve to the base of the femoral neck. Three major ligaments reinforce it.

The iliofemoral ligament of Bigelow lies anteriorly and has an inverted Y-shape. It tightens with hip extension.

The pubofemoral ligament, which covers the inferior and medial aspect of the hip joint capsule, tightens with hip extension and abduction.

The ischiofemoral ligament lies posteriorly, and its fibers spiral upward to blend with the zona orbicularis, a band that courses circumferentially around the femoral neck. It also tightens with extension, which explains why some degree of hip flexion increases capsular laxity.

The hip joint is least stable in the flexed position, in which the capsular ligaments slacken.

Normal hip range of motion includes the following (FIG 1):
- Abduction and adduction (50/0/30 degrees)
- Internal and external rotation (40/0/60 degrees)
- Flexion and extension (15/0/120 degrees)
- The muscular attachments surrounding the hip are extensive: a total of 27 muscles cross the joint.
- The primary flexors are the iliacus, psoas, iliocapsular, pectineus, rectus femoris (direct and indirect heads), and sartorius muscles.

The extensors are the gluteus maximus, semimembranosus, semitendinosus, biceps femoris (short and long heads), and adductor magnus (ischiocondyle part) muscles.

The abductors are the gluteus medius and minimus muscles, the tensor fascia lata, and the iliotibial band.

The adductors are the adductor brevis, adductor longus, and gracilis muscles and the anterior part of the adductor magnus muscle.

The external rotators are the piriformis, quadratus femoris, superior gemellus, inferior gemellus, obturator internus, and obturator externus muscles.

The blood supply originates from the common iliac arteries, which diverge and descend lateral to the common iliac veins and slightly posterior and medial to the common iliac veins. At the pelvic brim, the common iliac artery divides into the internal and external iliac arteries.

From the internal iliac system, the superior and inferior gluteal arteries and the obturator artery supply the psoas major and quadratus lumborum muscles, the pelvic viscera, and parts of the bony pelvis.

The acetabulum receives its blood supply from branches of the superior and inferior gluteal arteries, the pudendal artery, and the obturator anastomoses, all of which are branches of the internal iliac artery.

The external iliac artery continues to follow the iliopectineal arch divides the space between the inguinal ligament and the coxal bone. The lacuna musculorum, which is lateral to the iliopectineal arch, contains the iliopectineal muscle and femoral nerve. The lacuna vasorum, which is medial to the iliopectineal arch, contains the femoral artery and vein.

From the external iliac system, the medial and lateral femoral circumflex artery anastomoses around the proximal femur.

The medial femoral circumflex artery has three main branches: ascending, deep, and trochanteric.
- The deep branch is the primary blood supply to the femoral head. Its course starts between the pectineus and iliotibial band along the inferior border of the obturator externus.
- The trochanteric branch sprouts off at the proximal border of the quadratus femoris to the lateral trochanter.
- Posteriorly, the deep medial femoral circumflex artery enters between the proximal border of the quadratus femoris and inferior gemellus, then travels anterior to the obturator internus and superior gemellus, where it perforates the capsule. It then gives rise intracapsularly to two to four superior retinacular vessels. The deep branch of the medial femoral circumflex artery has several anastomoses: with the descending branch of the lateral femoral circumflex artery at the base of the femoral neck; with the deep branch of the superior gluteal artery at the insertion of the gluteus medius; with the inferior gluteal artery along the inferior border of the piriformis, posterior to the conjoined tendon; and with the pudendal artery near the retroacetabular space.
- The lateral femoral circumflex artery, the metaphyseal artery, and the medial epiphyseal artery contribute little to the vascularity of the femoral head.
Pelvic innervations of the lumbar plexus: L1, L2, L3, L4
- The femoral nerve, located on the anteromedial side of the iliopsoas muscle, passes under the inguinal ligament as it enters the thigh.
- The lateral cutaneous nerve emerges from the lateral border of the psoas major at about its middle, and crosses the iliacus muscle obliquely, toward the anterosuperior iliac spine. It then passes under the inguinal ligament and over the sartorius muscle into the thigh, where it divides into an anterior and a posterior branch.
- The anterior branch becomes superficial about 10 cm below the inguinal ligament, and divides into branches that are distributed to the skin of the anterior and lateral parts of the thigh, as far as the knee. The terminal filaments of this nerve often communicate with the anterior cutaneous branches of the femoral nerve and with the infrapatellar branch of the saphenous nerve—forming, with them, the patellar plexus.
- The posterior branch pierces the fascia lata and subdivides into filaments, which pass backward across the lateral and posterior surfaces of the thigh, supplying the skin from the level of the greater trochanter to the middle of the thigh.
- The obturator nerve is located in the fascia directly under the pubic bone. The femoral and obturator nerves also travel with their arteries anteriorly and medially, respectively.

Pelvic innervations of the lumbosacral plexus: L4, L5, S1, S2, S3
- The sciatic nerve travels without any significant arterial counterpart out to the greater sciatic foramen, with the posterior femoral cutaneous and other small nerves, to the short external rotators.
- The superior gluteal nerve exits the pelvis via the suprapiriform portion of the sciatic foramen along with the superior gluteal vessels.
- Palsy results in abductor lurch, also known as a Trendelenburg gait.
- The inferior gluteal nerve exits the pelvis via the infrapiriform portion of the sciatic foramen along with the superior gluteal vessels.
- Palsy results in difficulty in rising from a seated position and climbing stairs due to weakness of hip extension.

PATHOGENESIS
- The mechanical cause of osteoarthritis is secondary to several conditions, including:
  - Developmental dysplasia of the hip. A maloriented articular surface with deficient anterior or global coverage of the femoral head and decreased contact area leads to excessive and eccentric loading of the anterosuperior portion and subsequently promotes the development of early osteoarthritis of the hip.\(^{10,17,26}\)
  - Acetabular retroversion can result from posterior wall deficiency or excessive anterior coverage, or both, and contributes to osteoarthritis.\(^{1,2,20,22}\)
  - Abnormal contact between the proximal femur and the acetabular rim during terminal motion of the hip leads to lesions of the acetabular labrum or the adjacent acetabular cartilage. This phenomenon is more common in young and physically active adults. The early chondral and labral lesions continue to progress, resulting in degenerative disease. It has been found in a variety of hip conditions more commonly than has been previously noted, including dysplasia, Legg-Calvé-Perthes disease, and post-pelvic osteotomies.
  - The posterior aspect of the acetabulum is subjected to high loads during the activities of daily living. With acetabular retroversion, theoretically greater unit loads are imposed on the available posterior cartilage, which may be responsible for the development of osteoarthritis of the hip.\(^7\)
  - Joint hyperlaxity, as in Down syndrome
- These patients have hips with a substantial structural deformity that predisposes the hip to dynamic instability, localized joint overload, impingement, or a combination of these factors, which results in intra-articular disease and premature secondary osteoarthritis.

NATURAL HISTORY
- The anatomy of the hip joint and the development of degenerative joint disease are related.
  - Femoroacetabular impingement is caused by overcoverage of the acetabulum (ie, retroversion). The repeated insult leads to degenerative arthritis, rendering a joint-preserving procedure much less predictable and quality of the results dependent on the extent of cartilage damage.
  - Developmental dysplasia of the hip
    - Dysplasia without subluxation. Patients usually present because of an incidental finding of dysplasia on a radiograph or because they become symptomatic. Evidence supports the idea that dysplasia will result in degenerative joint disease in adults, particularly in women.\(^4\) Increased contact stresses at the joint interface are postulated to be the cause of articular degeneration.
    - Dysplasia with hip subluxation usually is accompanied by significant degenerative changes around the third or fourth decade of life.
    - The prevalence of osteoarthritis by the age of 50 years has been reported to be 43% to 50%\(^{26}\) in patients who have dysplasia and 53%\(^{15}\) in those who have Perthes disease.
- Using a technique that respects the blood supply to the acetabular fragment and promotes adequate reorientation can modify the natural history of the osteoarthritis. Improvement of the insufficient coverage of the femoral head, reduction of mediolateral displacement, and correction of the version of the fragment are the main approaches to correcting malalignments of the hip.

PATIENT HISTORY AND PHYSICAL FINDINGS
- Determining the etiology of hip pain can be difficult. Both extra- and intra-articular hip structures can give rise to pain, which can be referred to the groin, the lateral trochanteric region, or the lateral, medial, or anterior thigh, as well as the posterior pelvis, buttock, and lower back.
- The history for patients with intra-articular hip pathology can range from an acute twisting or falling episode to the insidious onset of pain that increases over months to years. Many important symptoms may not be readily volunteered by the patient, but must be sought by the orthopedist.
The mechanically abnormal hip can either be asymptomatic or present with pain, limping, a sense of weakness, or feelings of instability, snapping, and locking.

- The pain from arthritis occurs with weight bearing, with the first few steps after a period of immobilization, and is localized to the groin.
- The pain from abductor fatigue is localized to the posterior iliac crest or over the abductor muscles. It may radiate as far distally as the knee.
- Earlier stages of osteoarthritis secondary to dysplasia
- Imbalance due to overgrowth of the greater trochanter: coxa breva and coxa vara, Legg-Calvé-Perthes disease
- The pain caused by osteoarticular impingement depends on the activity and on the position of the limb.
- May be exacerbated by combining flexion, adduction, and internal rotation
- Occurs after the person has been sitting for a long period
- The “C sign” is diagnostic: the patient places the index finger over the anterior aspect of the hip and the thumb over the posterior trochanteric region to indicate the location of their pain.
- The acute pain related to acetabular rim syndrome is a sharp, sudden pain in the groin, often associated with a strong sense of instability or locking.
- Instability is described as a feeling that the joint is unstable.
- Snapping, locking, and clicking are common symptoms. A true locking of the hip is a sign of labral disease. Painless clicking can occur as the iliopsoas tendon snaps over the uncovered anterior femoral head, an occurrence that may be associated with dysplasia.

The physical examination includes the evaluation of stance, gait, limb lengths, strength, and range of motion, and special tests.

- Patients with intra-articular pathology may stand with the hip flexed and walk with an antalgic gait with a shortened stance phase and shortened stride length.
- In the presence of acetabular dysplasia, internal rotation of the hip often is increased because of excessive anteversion of the femoral neck.
- If internal rotation is decreased, the patient may have secondary osteoarthritis.
- The Trendelenburg test
- Specific tests include:
  - The impingement test. The hip is rotated internally as it is flexed to 90 degrees and adducted 15 degrees. This brings the anterior femoral neck in contact with the anterior rim of the acetabulum, which is the usual site of overload in acetabular dysplasia. The test is positive in patients with acetabular rim syndrome. The patient’s pain typically is in the groin.
  - The apprehension test. The hip is extended and externally rotated. This produces a feeling of discomfort and instability in patients who have anterior uncovering of the femoral head.
  - Moving the hip from full flexion, external rotation, and abduction to a position of extension, internal rotation, and adduction can recreate pain and snapping in patients with anterolateral labral tears and iliopsoas snapping hip.
  - Pain with supine log-rolling of the hip is the most specific test for intra-articular pathology.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Plain radiography includes an AP view of the pelvis, a false-profile view, a cross-table view, and a functional view in abduction of the affected hip (FIG 2).
- The AP radiograph of the pelvis is the view that gives the most information.
  - It is taken with the patient standing, allowing an assessment of the hip during load-bearing.
  - It must be in neutral rotation and without any pelvic tilt.
  - Shenton’s line is assessed, because discontinuity suggests hip subluxation secondary to hip dysplasia (FIG 3).
  - The presence of an acetabular rim fracture may suggest rim overload.
  - The hip space and the presence of any degenerative changes also are assessed.
  - The degree of dysplasia is assessed by the following measurements:
    - The center-edge angle of Wiberg: an angle subtended by a line from the center of the femoral head to the lateral acetabular margin, and a vertical line from the center of the femoral head. It also is known as the lateral center edge angle, and is greater than 25 degrees in nondysplastic hips.
    - The Tonnis angle: the inclination of the weight-bearing zone of the acetabulum. In normal hips, it should be less than 10 degrees (see Fig 3).
Acetabular version: assessed by identifying the anterior and posterior rims of the acetabulum. If the anterior line crosses the posterior line (the cross-over sign), the acetabulum is retroverted.

The false-profile view of Lequesne and de Sèze is obtained with the patient standing with the affected hip on the cassette, with the pelvis rotated 65 degrees from the plane of the radiographic film and with the ipsilateral foot parallel to the film. The beam is centered on the femoral head perpendicular to the cassette.

This view allows assessment of the anterior coverage of the femoral head. The ventral inclination angle can be measured by a line from the center of the femoral head to the anterior acetabular margin, and a vertical line from the center of the femoral head. It also is known as the anterior center edge angle. In normal hips the angle will be greater than 25 degrees.

The functional view in abduction is taken with the hip in maximal abduction. It simulates the potential correction for osteotomy. The hip should be congruent, reduced, and covered.

CT scans provide three-dimensional information with a clearer indication of the lack of coverage than plain radiographic indices.

The ideal position of the hip is full extension and 15 degrees of external rotation.

MRI
- MR arthography helps to analyze the acetabular labrum and the features related to abnormal loading.
  - Hypertrophy, dysplasia
  - Degeneration
  - Tears
- Findings such as cartilage loss, labral lesions, and cyst formation can be predicted based on preoperative radiographic findings.
- These findings may be useful in alerting the surgeon to the location and nature of intra-articular disorders that could be addressed at the time of arthrotomy.

SURGICAL MANAGEMENT
- Indications for PAO
  - Symptomatic severe acetabular dysplasia (grade IV or V) according to Severin’s classification
  - Symptomatic anterior femoroacetabular impingement due to acetabular retroversion
  - Minimal or no secondary osteoarthritis
  - Young, healthy patient
  - Adequate congruency of the hip joint
  - Adequate hip flexion (100 degrees) and abduction (30 degrees)

- Contraindications for PAO
  - Moderate to advanced secondary osteoarthritis-grade 2 or 3
  - Older age
  - Major hip joint incongruity
  - Obesity
  - Major restriction of hip motion (hip flexion of less than 100 degrees or abduction of less than 30 degrees, unless a proximal femoral procedure is planned to address femoroacetabular impingement)
  - For rotational osteotomy
    - CE angle lower than 40 degrees
    - Acetabular roof inclination greater than 60 degrees
    - Femoral head deformity inaccessible for correction
  - Major medical comorbidities
  - Patient noncompliance

Preoperative Planning
- A complete history is obtained, and a physical examination is performed.
  - The location of, quality of, and activities associated with hip pain are recorded.
  - Gait pattern, leg length, and range of motion are documented.
- Appropriate medical and anesthetic evaluation is performed.
- Preoperative neurovascular status is documented.

- Radiographic examination
  - AP view of the pelvis
  - True lateral: Dunn views, 45 and 90 degrees
  - False-profile: Lequesne and de Sèze view
  - The functional view in abduction with internal rotation may indicate the amount of correction possible.

Positioning
Bernese Periacetabular Osteotomy
- The patient is positioned supine on a radiolucent table.
- A footrest is secured to the table to assist in holding the extremity in a position of hip flexion.
- The ipsilateral upper limb rests over the chest.
- The limb is prepared and draped from above the iliac crest to the foot to allow wide access to the hemipelvis.
- If needed, nerve-monitoring leads are placed and secured on the involved extremity, over-wrapped with stockinette and an adhesive wrap.

Approach
- The Bernese PAO is a modified Smith-Petersen approach, a direct anterior approach that combines the iliofemoral and ilioinguinal approaches, preserving the abductor muscle attachments.
BERNESE PERIACETABULAR OSTEOTOMY

Incision, Dissection, and Iliac Spine Osteotomy

- The Bernese PAO is a modified Smith-Petersen approach that starts with a skin incision that describes a gentle medial curve from 3 cm proximally to 10 cm distally to the anterosuperior iliac spine (TECH FIG 1A).
- Subcutaneous flaps are raised medially and laterally, aiming to identify the fascia over the tensor fasciae latae muscle belly.
- The interneural space between the tensor fasciae and the sartorius is developed by incising the fascia in line with the muscle fibers, protecting the lateral femoral cutaneous nerve, which stays within the sartorius fascia.
- The aponeurosis of the external oblique muscle is reflected medially off the iliac crest.
- The anterosuperior iliac spine is osteotomized about 15 mm proximally on the iliac crest, preserving the origin of the sartorius and the ilioinguinal ligament (TECH FIG 1B).
- Proximally to the osteotomized site, the periosteum on the medial edge of the iliac crest is incised and reflected medially with the origin of the iliacus muscle.
- The conjoint tendon of the rectus muscle is transected and reflected distally, leaving a stump of tendon in the anterior inferior iliac spine for later repair.
- A plane over the anterior hip capsule and under the psoas tendon is developed by reflecting off the iliacus muscle fibers.
- The hip capsule is exposed anteriorly and inferomedially, with the exposure facilitated by hip flexion.

Ischial Osteotomy

- Following the capsule posteriorly, the anterior aspect of the ischium is palpated with scissors that dissect the infractyloid groove and identify the limits:
  - Hip capsule, superiorly
  - Obturator foramen, medially
  - Origin of the ischiotibial muscles, laterally
  - The scissors are used to protect and favor the entrance of a curved (or angled), pronged, 1.27-cm osteotome.
  - The osteotome is positioned in the infractyloid groove and is checked with AP and 45-degree oblique fluoroscopy views.
  - The infra-acetabular osteotomy starts just distal to the inferior lip of the acetabulum and aims toward the middle of the ischial spine.
- At the same AP plane, the osteotome progresses as follows:
  - Through the medial cortex up to approximately 1 cm anterior to the posterior cortex
  - Through the central part of the ischium
  - Onto the lateral cortex, which is the least deep portion and needs no more than 20 mm of penetration (TECH FIG 2). Abduction of the hip minimizes the risk of sciatic nerve injury during this cut.

Pubic, Iliac, and Posterior Column Cuts

- Hip flexion and adduction now facilitate exposure of the pubic ramus.
- The periosteum is incised along the superior cortex, and a pair of narrow curved retractors are placed around the anterior and posterior aspects of the pubic ramus, protecting the obturator nerve. A third spiked retractor is impacted into the superior cortex at least 1 cm medial to the medial-most extent of the iliopsoas muscle, retracting the iliopsoas and the femoral neurovascular bundle medially.
- The pubic cut is oriented from anterosuperior and lateral to posteroinferior and medial, avoiding creating a bony spike in the mobile fragment (TECH FIG 3A). It can be initiated with a small oscillating saw or a burr into the anterosuperior cortical, just lateral to the spiked retractor.
- The posteroinferior cortical cut is completed with a straight or angled osteotome.
- The periosteum must be released all around, allowing the correction.
- To make the iliac cut, the ileum and the quadrilateral surface of the pelvis are stripped subperiosteally. The sciatic notch is identified with a large Hohmann retractor.
- The lateral cortex of the ileum is assessed from its crest by detaching a small portion of the periosteum, allowing the insertion of a blunt retractor to protect the abductor muscles during the iliac osteotomy.
- A high-speed burr is used to make a target hole approximately 1 cm superolateral to the pelvic brim.
- The iliac cut is then made with an oscillating saw, first along the medial cortex and then, with the lower extremity abducted, into the lateral cortex (TECH FIG 3B).
- For the posterior column cut, the column is exposed with the straight cobra retractor along the inner aspect of the true pelvis toward the ischial spine.
■ The cut into the medial cortex is made by a straight osteotome at an angle of 120 degrees to the iliac cut (TECH FIG 3C) under fluoroscopic monitoring.
■ The cut is then completed with a straight osteotome that extends 5 to 6 cm down or an angled osteotome that goes from medial to lateral in three or four steps (TECH FIG 3D).

Mobilization and Correction
■ A Schanz pin is placed in the supra-acetabular region, and the mobility of the fragment is tested (TECH FIG 4).
■ Lack of full mobility indicates the need to review three sites:
  ■ The periosteum around the pubic ramus
  ■ The posterior cortex at the 120-degree pivot point
  ■ The infra-acetabular cut

■ A bone spreader inserted into the iliac cut can be used as an auxiliary to the Schanz pin.
■ The correction is then carried out in whatever plane, aiming for a suitable position.
■ The superior pubic ramus is accessed, and the acetabular fragment is tilted anterolaterally to ensure that it can be completely unlocked.
■ The acetabulum is then repositioned with internal rotation and some forward tilt extension.
■ Translation of the fragment should be:
  ■ Medially, as desired. This can be achieved with some direct pressure from the lateral side with a pointed Hohmann retractor. Care is taken to maintain or restore anteversion.
  ■ Superiorly, in an attempt to achieve bone-to-bone contact with the overlying ilium and to minimize
The definitive fixation is carried out using three or four 4.5-mm cortical screws (TECH FIG 5). One screw is placed into the anterolateral aspect of the acetabular fragment to act as a “blocking” screw. Two or three additional screws are placed progressively more medially. Fluoroscopic images are made again to confirm the acetabular reduction and the position of fixation hardware. Range of motion is assessed to rule out secondary femoroacetabular impingement and instability. Hip flexion must be greater than 90 degrees. Joint stability is assessed by extension, abduction, and external rotation.

Wound Closure

The prominent aspect of the anterior acetabular fragment is trimmed with an oscillating saw; the trimmings are used to fill up the iliac gap. The lateral femoral cutaneous nerve is better protected when retracted medially with the sartorius muscle. Subperiosteal dissection at the superolateral pubic ramus protects the obturator nerve. A pubic osteotomy must be performed medial to the iliopectineal eminence. AP radiographs must be evaluated for the lateral center edge angle, the acetabular inclination, the medial translation of the hip-joint center, the position of the teardrop, and the version of the acetabulum. Slight undercorrection is preferred to excessive correction.

PEARLS AND PITFALLS

Approaching through the anterosuperior iliac spine osteotomy anticipates the bone quality. The lateral femoral cutaneous nerve is better protected when retracted medially with the sartorius muscle. Subperiosteal dissection at the superolateral pubic ramus protects the obturator nerve. A pubic osteotomy must be performed medial to the iliopectineal eminence. A periosteal sleeve around the pubic ramus may prevent free mobilization of the acetabulum fragment. Fluoroscopic images may lead to suboptimal correction. Joint violation may occur in the pubic, ischium, and posterior column cuts.
Free mobility of the fragment is essential. Lack of mobility is more likely to be an incomplete osteotomy. The patient should be well positioned to obtain a radiograph in the correct AP pelvis view.

If the lateral femoral cutaneous nerve is damaged in the course of the procedure, it is better to resect and cauterize it because of the morbidity associated with its recovery. An oscillating saw is less likely to cause uncontrolled fracture in the ilium cut.

Hip flexion–adduction protects anteromedial vascular structures (ie, femoral, obturator, superior gluteal). Hip extension protects the sciatic nerve. Releasing the anterior rectus femoris from the anterior inferior iliac spine reduces the risk of femoral nerve injury. The center of rotation should be corrected by medializing the acetabular fragment.

**POSTOPERATIVE CARE**

- **Pain control**
  - The hip is placed in neutral position in a soft splint.
  - Pain control should be compatible with the perioperative regimen.
  - A multimodal analgesic regimen utilizing regional blockade, nonsteroidal anti-inflammatory drugs, and other peripheral and centrally acting analgesics, including α-2 agonists, ketamine, α-25 ligands, and opioids is one of the most efficacious strategies for reducing pain following the surgery.
  - Use pain-rating scales—visual or color analogues—before discharging the patient at the 5th or 6th day.
  - The suction drains are removed after 48 hours.
  - Thromboembolism prophylaxis follows many protocols.
    - Chemoprophylaxis
      - Low-molecular-weight heparin during hospitalization
      - Mechanical prophylaxis
      - Intermittent pneumatic compression to the calves
  - Heterotopic ossification prophylaxis—facultative
    - Not necessary when preserving the soft tissue around the hip
    - For at-risk situations: indomethacin, 25 mg three times per day
  - Physical therapy
    - Should be simple, emphasizing function more than strengthening or range of motion
    - The patient is out of bed on the third postoperative day.
    - Partial weight bearing (10 kg) is begun with crutches.
    - Active movements that could jeopardize the reinsertion of the musculature are discouraged for 6 weeks.
    - Resistive exercises are avoided for 12 weeks.
    - After 8 to 10 weeks, walking is allowed with a cane, which should be used until the abductors are strong enough to stabilize the hip.
  - Consolidation
    - Radiographs should be taken and analyzed immediately postoperatively, at 6 weeks, and again at 12 weeks.

**OUTCOMES**

- Reduction in pain and preoperative limp has been universal, though the degree of reduction has depended on the amount of preoperative osteoarthritis.

**COMPLICATIONS**

- Complications can be classified as trivial, moderate, or major:
  - Trivial—those of little clinical importance that require no treatment
    - Pubic non-union
    - Reduced lateral femoral cutaneous sensation
    - Asymptomatic heterotopic ossification
  - Moderate
    - Minor wound complications
    - Minor medical complications
    - Peroneal nerve neuropraxis
    - Fractures not requiring treatment
  - Major—those with the potential for significant morbidity
    - Nerve palsy with permanent impairment
    - Major bleeding
    - Reflex sympathetic dystrophy
    - Loss of fixation
    - Deep venous thrombosis
    - Deep infection
- Complications, and their severity, are commonly linked with the surgeon’s learning curve.
- Technical complications have been analyzed and correlated with some specific steps of the procedure.

- **Surgical approach**
  - Nerve injury: the lateral femorocutaneous is most commonly injured (30% of patients).
  - Acetabular necrosis: inferior branch of the superior gluteal artery and the acetabular branches, from inferior gluteal artery injuries
  - Previous procedures increase the risk.

- **Osteotomy**
  - Intra-articular osteotomy
    - Ischium: most common on superolateral femoral head migration
References

DEFINITION

- This chapter focuses on the use of intertrochanteric adduction (varus) osteotomy to reorient the proximal femur to improve femoral head coverage and hip joint congruency. Clinical conditions that constitute good indications for this operative technique are:
  - Mild epiphyseal dysplasia of the femoral head with the lateral part of the head intact
  - Circumscribed anteromedial necrosis or osteochondritis dissecans of the femoral head
  - Valgus head, in particular when the fovea lies within the weight-bearing zone of the hip joint
  - Developmental dysplasia of the hip, when the procedure is performed in conjunction with pelvic osteotomy to obtain better joint congruences
  - Posttraumatic joint incongruence
  - The prerequisite for a successful operative treatment is the possibility that the joint incongruence can be improved.
  - The same operative technique can be used for correction of the proximal femur in abduction, flexion and extension, and rotation, and every combination thereof.

ANATOMY

- The hip joint is a strong and stable multiaxial ball-and-socket synovial joint. In the standing position, the entire weight of the upper body is transmitted through the hips to the lower extremities.
- Because the depth of the acetabulum is increased by the fibrocartilaginous labrum, more than half of the femoral head fits within the acetabulum.
- The femoral head is covered with articular cartilage, except for the fovea.
- The central and inferior part of the acetabulum, the acetabular fossa, does not participate physiologically in transmission of weight force.
- The main blood supply of the femoral head is from the circumflex femoral arteries, especially the medial circumflex femoral artery, a fact that must be considered when operating in this area.

PATHOGENESIS

- A variety of pathologic processes can affect hip joint congruence. The most important of these are listed earlier in this chapter.
- Incongruences of the hip joint are associated primarily with a reduced weight-bearing area, which increases the load on the remaining joint surface.

NATURAL HISTORY

- If the joint load constantly exceeds the resistibility of the articular cartilage, arthrotic changes begin to develop. If untreated, this condition results inevitably in a progressive destruction of the hip joint.
- Current surgical treatment for advanced stages of this degenerative process is dominated by total hip replacement due to the overwhelming success of this intervention.

PATIENT HISTORY AND PHYSICAL FINDINGS

- To assess duration and severity of symptoms as well as potential actuating circumstances, a complete history must be taken, including childhood disorders such as developmental hip dysplasia, sustained Perthes disease, or slipped capital femoral epiphysis.
- General examination of the hip always should include active and passive range of motion as well as gait inspection and leg length comparison.
- Specific physical examination methods include:
  - Anterior impingement. The test is positive if the passive movement provokes groin pain, which relates to a femoroacetabular impingement at the anterior wall or a labral tear.
  - Apprehension test. The test is positive if the patient complains about a feeling of imminent joint luxation, which indicates an insufficient coverage of the femoral head.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- A plain, anteroposterior (AP) radiograph of the entire pelvis is needed to determine the type of pathology in the femoral head or the femoral neck. The patient is positioned with slight internal rotation of the hip to compensate for the femoral antetorsion.
- Other helpful projections are (1) an axial view, (2) the false-profile view as a true lateral projection of the femoral head and neck, and (3) an oblique view on the acetabulum tangential to its superoanteromedial edge (FIG 1).
- An AP radiograph of the hip in maximal abduction also may be helpful to determine the optimal degree of correction.
- It simulates the postoperative position of the femoral head and the expected joint congruency.
- Pelvic MRI or CT scans are optional. They may offer additional information on accompanying lesions on labrum or cartilage or the extent and stage of a femoral head necrosis.

SURGICAL MANAGEMENT

Preoperative Planning

- A preoperative drawing is mandatory. It should make it possible to determine the level and localization of the osteotomy, as well as entry point and direction of the implant in relation to reference points that can be identified intraoperatively.
- Because preoperative drawing is a crucial part of the operative technique, it is covered fully in the Techniques section.
Positioning
- A lateral decubitus position on the contralateral side is preferred, allowing unimpeded access to the operation field and free movement of the afflicted leg (FIG 3).
- Intraoperative fluoroscopy is strongly recommended. Therefore, a radiolucent operating table must be used, and the position of the C-arm and image intensifier should be checked before washing and draping.

Approach
- The standard procedure uses a lateral approach with an L-shaped detachment of the vastus lateralis muscle, thus increasing the gap medial to the abductors.
- Optionally a transgluteal approach also can be used, allowing a better view of the anterior joint capsule, but this approach is not recommended when an osteotomy of the greater trochanter is planned.
Preoperative Drawing

- Outlines of the femur and pelvis are transferred from the radiograph to drawing paper. Alternatively, computer programs are available that allow preoperative planning directly on digital images within a PACS (picture archiving and communications systems) viewer on the computer.
- The drawing should focus on the following (Tech Fig 1):
  - Identification of the innominate tubercle as the lateral, intraoperatively detectable reference point
  - Drawing of the planned osteotomy, perpendicular to the femoral shaft axis. The level of the osteotomy is determined by aiming at the cranial extension of the lesser trochanter.
  - Measurement of the distance between the osteotomy and the innominate tubercle
  - Determination of the point within dense bone trabeculae for optimal blade placement.
  - Blade position is now determined by that point and the designated correction angle relative to the planned osteotomy.
- The intersection point of the outlined blade position and the lateral cortex marks the entry point of the blade. Its distance to the innominate tubercle is measured and can be reproduced intraoperatively.
- An additional trochanteric osteotomy is recommended in intertrochanteric osteotomies (ITOs) with a correction angle of more than 25 degrees.
- The osteotomized trochanter should be at least 10 mm thick, and the angle of the resected wedge should be equal to the resection angle to allow an accurate apposition of the trochanter fragment.
- When transferring the plan to the surgical situs, it must be remembered that radiographs show a magnified projection of the real anatomy.
- Therefore, all measured distances (not angles) must be reduced by around 10%.

Tech Fig 1 • A. The osteotomy level is determined in relation to the innominate tubercle (IT), the point of dense bone trabeculae (D), and the blade position with the desired correction angle (l), after which the blade entry point (E) can be determined. The gray area represents the optional trochanteric osteotomy, which is recommended only when the correction angle exceeds 25 degrees. B. Final plate position after intertrochanteric adduction osteotomy without trochanteric osteotomy. C. Final plate position after an additional trochanteric osteotomy.
**TECH FIG 2 • Approach.** A. The skin incision is centered over the greater trochanter, starting 3 to 4 cm cranial of the tip of the trochanter and reaching 20 to 30 cm distally along the axis of the femur. B. Intraoperative view of the incision. The greater trochanter is marked as an anatomic landmark. C. The fasciotomy is performed longitudinal to the axis of the femur. D. After retraction of the fascia, the greater trochanter is exposed. E. L-shaped detachment of the vastus lateralis at its origin. F. Transgluteal approach as a variant. G. This approach allows a better view of the anterior capsule.
The mobilized muscle is retracted anteriorly to expose the lateral aspect of the femur up to the first perforating arteries, which usually are found 8 to 10 cm distal to the innominate tubercle. The vessels are ligated.

A transgluteal approach may be used as an alternative.
- Here, the anterior part of the gluteus medius and the anterior insertion of the gluteus minimus are detached, and the incision is continued into the vastus lateralis.

### BLADE CHANNEL PLACEMENT

- The anterior capsulotomy is performed in line with the femoral neck and extended to the labrum, which is preserved (TECH FIG 3).
  - This approach does not affect blood supply to the femoral head.
- Capsulotomy and exposure of the femoral neck and head are facilitated by insertion of as many as three Hohmann retractors (8 mm), which are inserted on the acetabular rim just proximal to the labrum with the hip in a slightly flexed position.
- At this time direct visual assessment of the femoral anteversion and part of the articular cartilage is possible, if the leg is externally rotated.
- At the level of the blade entry point, which was determined on the preoperative drawing in relation to the innominate tubercle, a cortical fenestration measuring $15 \times 5\,\text{mm}$ is made.
  - It lies almost completely anterior to an imaginary line dividing the lateral aspect of the greater trochanter into two equal parts.
- Previous marking of the window with a scalpel or an osteotome is recommended.
- The direction of the blade, which also was determined by the preoperative drawing, can now be measured with quadrangular positioning plates and marked with a K-wire inserted into the trochanter cranial to the cortical window.
- An additional K-wire is placed along the femoral neck and pushed into the femoral head to indicate the anteverision of the neck.
- Measurement should not be done too close to the origin of the vastus lateralis, because the diameter of the femur decreases significantly over a distance of 2 to 3 cm.
- The U-shaped seating chisel is inserted into the cortical windows with the direction defined by the two K-wires.
- It is recommended that the chisel be introduced only until it has obtained some purchase.
- The position is than checked in all planes and the chisel readjusted if necessary.
- The seating chisel is advanced under continuous control of all three alignments into the femoral neck and head until the desired depth has been reached (generally 50 to 60 mm).
- Before the osteotomy is performed, the chisel is withdrawn slightly to make it easier to remove it later.

**TECH FIG 3** - Blade channel placement. A. Anterior capsulotomy in line with the femoral neck. After visualization of the anteverision of the femoral neck, a cortical fenestration is made at the blade entry point. B. Placement of two K-wires shows the desired direction of the blade, along which the seating chisel is inserted into the cortical window.
OSTEOTOMY

- The level of the osteotomy is identified in relation to the innominate tubercle, according to the preoperative drawing.
  - An exact drawing obviates the need for palpation of the lesser trochanter.
- Two K-wires are placed into the femur in an anteroposterior direction, one proximal and one distal to the planned osteotomy to allow later rotational realignment (TECH FIG 4).
- The osteotomy is performed perpendicular to the long axis of the femur under continuous irrigation.
  - The surrounding soft tissues, in particular posteriorly, must be protected with blunt retractors.
  - The medial femoral circumflex artery runs approximately 15 mm proximal to the lesser trochanter, close to the bone, and can be easily injured.
  - If an additional trochanteric osteotomy is performed, anastomoses from the internal iliac artery may be severed, invariably causing necrosis of the femoral head.
  - It is recommended, therefore, that the anterior cortex be osteotomized first and the osteotomy completed posteriorly thereafter.
  - A broad chisel (20 mm) is inserted to spread the osteotomy gap.
  - The chisel and the patient’s foot are used as levers to mobilize the fragments in opposite directions.
  - Manipulation with the seating chisel in the femoral neck must be avoided, because this could lead to loosening.

TECH FIG 4 • Osteotomy. A. After placing two parallel K-wires proximal and distal of the planned osteotomy for later rotational control, the osteotomy is performed under protection of the surrounding soft tissue. B. Insertion of a broad chisel to spread the osteotomy. The chisel and the patient’s foot are used as levers to mobilize the fragments.

BLADE INSERTION

- Before the seating chisel is withdrawn, the blade-plate must be readily mounted on the inserter. Blade and inserter must be in line with each other.
  - For the first 2 to 3 cm, the blade is advanced manually with repeated pushes (TECH FIG 5).
  - As long as the blade follows the channel, easy advancement should be possible.

TECH FIG 5 • A. Insertion of the blade into the channel formed by the seating chisel. B. For the final 10 mm, the blade is advanced with the impacter.
Chapter 14  FEMORAL OSTEOTOMY

TECHNIQUES

CORRECTION AND PLATE PLACEMENT

- Achievement of the desired approximation between plate and lateral cortex of the femoral shaft can be facilitated by manipulation of the leg. For rotational realignment, the previously inserted K-wires are used as references.
- After the plate is positioned, it is held against the bone with a reduction forceps (Verbrugge forceps; TECH FIG 6).
- Fixation of the plate to the distal fragment can be achieved in three ways:
  - Without interfragmentary compression
  - With interfragmentary compression obtained by use of the gliding holes
  - With interfragmentary compression obtained with a plate tensioner
- The amount of compression depends on the degree of optimal stability as well as the surgeon’s preference.
- When using a plate tensioner, compression must be applied judiciously, because strong compression may cause a loss of correction, especially in a case of reduced bone quality.
- If no intertrochanteric osteotomy is performed, the use of gliding holes is recommended.
- Such contact is best prevented by positioning the thigh in adduction until ¾ of the blade has been introduced.
- Once the distance between offset of the plate and bone has reached 1 cm, the inserter is removed, and the blade is further advanced with the impactor until full contact with the bone is achieved.
- If an additional trochanteric osteotomy has been performed, the trochanter fragment is flipped over the blade through an already prepared window. The blade with the trochanter is then pushed into the femoral neck.
- Care must be taken not to split the trochanter fragment.

If the force necessary for insertion of the blade increases dramatically, the plate should be removed, the seating chisel again should be reintroduced, the direction should be checked, and the plate insertion repeated.

Hammer blows to advance the plate are allowed only after the direction of the blade has been confirmed. Otherwise, the blade can be pushed in the wrong direction or even perforate the femoral neck.

During blade insertion, contact of the plate with soft tissue or the femoral shaft must be avoided, because this might change the direction of the blade.

If further stability is needed, an additional screw can be inserted through the hole in the offset and engaged into the proximal fragment.

While the screws are being tightened, rotational alignment of the fragments must be closely observed.

External malrotation may occur when only the posterior rim of the plate is in contact with bone.

The stability of the fixation is checked once the first screw has been tightened and the reduction forceps is still in place.

The hip is put through a full range of motion, in particular of rotation with the hip in 90 degrees of flexion.

If the fixation proves to be stable, the second screw is inserted.

With good bone stock, two bicortical screws are sufficient.

In cases in which an additional intertrochanteric osteotomy is performed, the removed bone wedge is inserted into the lateral gap between the two main fragments.

The use of a plate tensioner is preferable, because its use reduces the risk of revalgization.

TECH FIG 6  *Correction and plate placement. A. After the desired correction is reached and full contact of the plate with the lateral femur is achieved, the plate is held in place with a reposition forceps, and the first screw is placed through the plate. B. With good bone quality two screws distal to the osteotomy are sufficient. If bone quality is reduced, another screw can be inserted through the offset of the plate for additional stability.
POSTOPERATIVE CARE
- The leg is positioned on a splint with hip and knee in slight flexion.
- The patient is taken off bed rest on day 1 or 2, with partial weight bearing (15 kg) for 8 weeks.
- Non-weight bearing, which necessitates that the operated hip be held in flexion, leading to increased strain on the osteotomy, should be avoided.
- Physical therapy is required only for gait training using canes.
- Indomethacin (75 mg once daily) is given for 3 weeks for the prevention of heterotopic ossifications.
- Radiographic follow-up is done after 6 weeks.
- At 6 weeks after the operation, strengthening exercises of the abductor muscles can be started.
- Final radiographic follow-up is done 1 year after surgery.
- The implant is removed only in case of symptoms such as soft tissue irritation or trochanteric bursitis, and not before 1 year since the surgery.

OUTCOMES
- Published studies after intertrochanteric adduction osteotomy for the treatment of hip dysplasia have reported good long-term outcomes, ranging from 63% to 87% after 21 to 26 years.
- Treatment of an avascular necrosis of the femoral head with an ITO can be expected to achieve good results in 65% to 90% of cases, depending on the radiographic stage of the AVN.
- Data are limited on patients with osteochondritis dissecans treated with an ITO. Radiologic incorporation was achieved in more than two thirds of all patients.

COMPLICATIONS
- Unsatisfactory correction
- Incorrect blade placement
- Malrotation
- Femoral head necrosis
- Delayed or non-union
- Heterotopic ossifications
- Femoral or sciatic nerve injury

DEFINITION

- Femoroacetabular impingement (FAI) is a pathologic condition in which structural abnormalities of the femoral head–neck junction or the acetabulum result in early degenerative changes in the nondysplastic hip.
- FAI is one cause of osteoarthritis of the hip, particularly in young people.
- Impingement of the femoral head upon the acetabular rim takes place during motion of the hip, particularly with flexion and internal rotation.
- Currently, surgical dislocation for the correction of intraarticular pathology is the gold standard for the treatment of FAI.

ANATOMY

- Treatment via surgical dislocation of the hip requires thorough knowledge of the course of the deep branch of the medial femoral circumflex artery (MFCA).
  - Any surgeon performing this surgery must be familiar with this specific vascular anatomy.
  - Failure to respect the deep branch of the MFCA will result in avascular necrosis of the femoral head.
- After branching off from the deep femoral artery, the deep branch of the MFCA runs between the pectineus and psoas muscles laterally and follows the inferior border of the obturator externus muscle. It then reaches the trochanter just proximal to the quadratus femoris muscle, where it gives off a trochanteric branch. It then crosses the tendon of the obturator externus muscle posteriorly and continues its course anterior to the superior and inferior gemellus muscles and the obturator internus tendon.
  - The MFCA perforates the capsular fold at the level of the piriform muscle and continues as the lateral epiphyseal arteries to the dorsolateral femoral head, where it enters the epiphysis proximal to the former growth plate.

PATHOGENESIS

- Depending on the site of the deformity, two mechanisms of impingement can be distinguished.
  - Cam FAI is caused by deformities of the femoral head (eg, pistol grip deformity, aspheric femoral head, slipped capital femoral epiphysis).
    - The aspherical head–neck junction is jammed into the acetabulum, leading to a labrocartilaginous separation and shearing of the acetabular cartilage from the subchondral bone (FIG 1A).
    - Cartilage damage can be extensive, with flaps or defects involving as much as 15 mm toward the center of the joint.
  - Pincer FAI is caused by local (eg, acetabular retroversion) or general (eg, coxa profunda, protrusio) acetabular overcoverage in the presence of a normal proximal femur, leading to a linear contact between the acetabular rim and femoral neck that results in degenerative tears and ossification of the labrum.
    - Only a narrow strip of acetabular cartilage is involved along the acetabular rim (FIG 1B).
  - Isolated cam or pincer FAI is rare. In most cases, a combination of both types is present.

NATURAL HISTORY

- The evidence increasingly indicates that FAI is a major cause of osteoarthritis. Although the specific identification of FAI as a cause for early osteoarthritis is new, earlier studies suggested that abnormal anatomic shapes of the femoral head and neck lead to osteoarthritis.

PATIENT HISTORY AND PHYSICAL FINDINGS

- FAI usually presents in active young adults with slow onset of groin pain that often starts after a minor trauma.
  - During the initial stages of the disease, the pain is intermittent and may be exacerbated by excessive demand on the hip, such as athletic activities or after extensive walking.
Often the pain is present after sitting for a prolonged period.

These symptoms often are thought to be of muscular origin and treated by physical therapy, including stretching.

The leading symptoms of FAI are groin pain with motion and limited internal rotation, although overall hip function is almost unaffected according to established scores.

Clinical examination of the hip usually is normal except for a positive impingement test and a limitation of internal rotation of the flexed hip.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

Plain radiographs, including anteroposterior (AP) views of the pelvis and a lateral cross-table view, should be obtained.

Acetabular orientation (eg, anteversion, retroversion) and the depth of the acetabulum (eg, coxa profunda, protrusio) are assessed on the AP pelvic view (FIG 2A).

For proper assessment of the acetabular shape and version, the central x-ray beam must be centered about 2 cm above the symphysis pubis.

Any rotation to the right or left must be avoided, because this can lead to over- or underestimation of acetabular retroversion.

The lateral cross-table view shows the anterior contour of the head–neck junction with offset deficiencies or anterior bumps (FIG 2B).

A Lauenstein or Dunn view is an acceptable alternative to a lateral cross-table view.

MR arthrography is highly sensitive for the detection of labral tears and less sensitive for cartilage damage.

Radial reconstructions along the axis of the femoral neck are important for verifying anterolateral offset problems.

Radial reconstructions in axes other than along the femoral neck are useless.

**DIFFERENTIAL DIAGNOSIS**

- Adductor strains
- Iliopsoas bursitis
- Osteitis pubis
- Sports hernias
- Nerve compression (eg, lateral femoral cutaneous nerve, iliounguinal nerve, obturator nerve)
- Referred lumbosacral pain
- Intra-abdominal disorders (eg, appendicitis, diverticulosis)
- Genitourinary disorders (eg, urinary tract infection, nephrolithiasis, scrotal and testicular abnormalities, gynecologic abnormalities)

**NONOPERATIVE MANAGEMENT**

Conservative treatment may include rest until symptoms subside together with the administration of nonsteroidal inflammatory drugs.

Activities that lead to groin pain should be discontinued, and modification of activities is necessary, avoiding flexion and internal rotation.

Physical therapy, with the aim of improving range of motion, is contraindicated; it most often leads to an increase of symptoms and occasionally may accelerate joint degeneration.

Muscle-strengthening exercises can be beneficial.

**SURGICAL MANAGEMENT**

Preoperative Planning

All imaging studies are reviewed.

On the standardized AP view of the pelvis, the acetabulum is scrutinized for global (ie, coxa profunda, protrusio) or localized (ie, retroversion) overcoverage, rim fractures, labral ossifications, and osteophytes.

Acetabular coverage is assessed. Measuring the preoperative lateral center edge angle (LCE) and drawing the lowest acceptable LCE (usually 25 degrees) makes it possible to determine the amount of bone (in millimeters) that can be resected from the lateral acetabular rim.

The femoral side is observed for lateral asphericity (ie, pistol grip deformity), coxa vara or valga, and osteophytes.

The lateral cross-table view is assessed for the presence of an anterior offset deficiency (alpha-angle) or a bump.

The MR arthrograph is reviewed for the presence and location of labral and cartilage damage, and the exact location and size of the asphericity or bump are determined on the radial reconstruction in the axis of the femoral neck.
The patient is stabilized with three or four side-supports. The posterior support is placed against the sacrum, and the anterior support is slightly cephalad to the pubic symphysis.

The lower leg is placed in a tunnel bolster to avoid pressure sores and to provide a flat bearing for the upper mobile leg.

Disinfection includes the entire leg and is extended up to the lowest rib.

The leg is draped mobile, starting from the iliac crest and ending at the mid-thigh.

Both the anterior superior iliac spine and the posterior superior iliac spine should be freely palpable.

A sterile bag is placed anteriorly at the level of the knee for later positioning of the leg during dislocation of the hip.

### Approach

- Kocher-Langenbeck or Gibson approach with osteotomy of the greater trochanter

### Incision and Dissection (Gibson Approach)

- A straight skin incision is made, centered over the greater trochanter and running through the anterior third.
  - The length of the incision is about 20 cm, depending on the patient’s size and body mass index.
  - The subcutaneous tissue is cut, using careful hemostasis, down to the iliotibial band and the fascia over the gluteus maximus muscle.

- The anterior border of the gluteus maximus muscle is identified, marked by perforating branches of the superior gluteal artery that run within a thin fascia between the gluteus medius and maximus muscles and perforate the fascia lata overlying the gluteus maximus and medius.

- Because the blood vessels are accompanied by branches of the inferior gluteal nerve for the anterior portion of the gluteus maximus, the fascia is kept with the gluteus maximus to protect these structures.

- Proximally, the gluteus maximus muscle is detached from the gluteus medius almost up to the iliac crest, but the skin incision does not necessarily extend so far proximally.
  - Distal to the greater trochanter, the fascia is split in line with the femur.
  - The space between the gluteus medius and maximus muscles is opened, and the posterior border of the gluteus medius is visualized.

- Alternatively, the fibers of the gluteus maximus muscle can be split, as in a Kocher-Langenbeck approach. In this case, the skin incision has to be matched.

- The gliding tissue of the greater trochanter, including the bursa, is incised at the posterior border of the greater trochanter and is then reflected anteriorly, allowing visualization of the vastus lateralis ridge (TECH FIG 1).

- At this point, the trochanteric branch of the MFCA can be seen and coagulated before the trochanteric flip osteotomy is performed.

- The hip is rotated internally (20 to 30 degrees), and the posterior borders of the gluteus medius muscle and the greater trochanter are identified.

![TECH FIG 1](image1) • Right hip. The posterior border of the gluteus minimus muscle and the greater trochanter is prepared. The trochanteric branch of the MFCA is visible.

### Trochanteric Osteotomy

- Using a thin, oscillating saw blade, the osteotomy starts at the posterosuperior edge of the greater trochanter, about 5 mm anterior to the most posterior insertion of the gluteus medius muscle onto the tip of the trochanter, and runs distally toward the posterior border of the vastus lateralis muscle, ie, the vastus lateralis ridge (TECH FIG 2A,B).

- The osteotomy should stop at the anterior cortex.

- The fragment is levered with an osteotome, and a controlled fracture is obtained, leaving an anterior ridge, which increases stability of the trochanter after fixation.

- The correct inclination of the osteotomy is parallel to the leg. The fragment is about 15 mm thick.

Alternatively, a stepcut osteotomy can be performed (TECH FIG 2C).

- Using a thin, narrow, oscillating saw, the osteotomy starts proximally as already described, but stops at the midpoint between the tip of the greater trochanter and the vastus lateralis ridge.

- A second osteotomy is then performed, starting 3 to 4 mm posterior to the end of the proximal cut, aiming at the posterior border of the vastus lateralis muscle.

- The bone bridge between the two saw cuts is osteotomized using a 5-mm osteotome.

- A controlled fracture of the anterior cortex is obtained as described earlier in the chapter.
**Exposure**

- A small Hohmann retractor is placed over the anterior edge of the stable trochanter.
  - The remaining fibers of the gluteus medius and vastus lateralis muscles are released from the stable trochanter proximally and from the femur distally.
- Anterior to the posterosuperior tip of the trochanter, a fat pad becomes visible.
  - After it is incised, the piriformis tendon and its insertion onto the stable trochanter can be seen.
- Occasionally, fibers of the piriformis tendon remain attached to the trochanteric fragment and must be cut to allow further mobilization of the trochanter.
- The leg is now flexed and externally rotated, allowing more anterior retraction of the trochanter.
  - The vastus lateralis and the vastus intermedius are lifted off the lateral and anterior aspects of the proximal femur.
- The gluteus medius muscle is gently retracted in an anterosuperior direction, providing exposure of the piriformis and gluteus minimus muscles.
  - Note that the sciatic nerve crosses underneath the piriformis and avoid injuring it.
  - However, variations of the course of the sciatic nerve with respect to the piriformis muscle are common.
- The interval between the piriform and gluteus minimus muscles is developed.
  - Care must be taken to remain proximal to the piriform tendon to avoid damaging the deep branch of the MFCA.
  - The gluteus minimus is sharply dissected from the underlying capsule and is retracted anteriorly. Anteriorly, the tendinous insertion into the joint capsule must be divided.
  - Now the posterior, superior, and, finally, the anterior joint capsule are exposed (TECH FIG 3A).
  - The insertions of the short external rotator muscles and the piriformis muscle are left intact to protect the deep branch of the MFCA.
- A Z-shaped capsulotomy for the right hip and an inverse Z-shaped capsulotomy for the left hip are performed (TECH FIG 3B), taking care not to injure labrum and cartilage.
  - The longitudinal limb of the capsulotomy is performed parallel to the axis of the femoral neck, starting at the anterosuperior edge of the stable trochanter. Medially, the capsulotomy is in line with the anterior intertrochanteric line, leaving a cuff of capsular tissue for later reattachment, and extends down toward the lesser trochanter, but stops anterior to it to avoid injury to the MFCA, which runs posterosuperior to the lesser trochanter.
  - The proximal transverse limb of the incision is performed by incising the capsule along the superior acetabular rim until the piriform muscle is reached.
  - These steps keep the limb away from the capsular perforation of the MFCA.
  - The femoral head is dislocated anteriorly to allow inspection of the acetabulum.
  - Flexion and external rotation are used to place the leg in the sterile side bag (TECH FIG 3C,D).
  - With traction on a bone hook around the calcar, the femoral head is dislocated, and curved scissors are used to cut the ligamentum capitis femoris.
  - External rotation aids in opening up the anterior joint space and tensioning the ligament for easier transsection.
  - Lowering the knee lets the femoral head rise automatically out of the surgical site, allowing its full inspection.
  - Two blunt Hohmann retractors are placed around the neck (TECH FIG 3E).
  - To view the acetabulum, the knee is brought higher than the pelvis, and a gentle axial push allows the head to...
come posteriorly, creating enough space to visualize the entire acetabulum.
- Three retractors are inserted.
  - One double-angled Hohmann retractor is placed over the anterior rim of the acetabulum between labrum and capsule.
  - A second straight Hohmann retractor (8- or 16-mm) is placed on the anterosuperior rim, close to the anterior inferior iliac spine.
- An easy rider or cobra retractor is placed with the tip into the teardrop, retracting the femoral neck posteroinferiorly to gain further access to the posterior and inferior parts of the acetabulum.
- Now, a full view of the acetabulum is obtained (TECH FIG 3F).

**TECH FIG 3** • A. The trochanteric fragment is mobilized anteriorly. The joint capsule is prepared. The insertion of the piriformis tendon onto the trochanter is intact. B. Schematic of the capsulotomy. C. By flexion and external rotation, the leg is placed in the anterior side bag. This maneuver allows anterior dislocation of the hip. D. Overview across the acetabulum after dislocation of the hip. E. Dislocated femoral head. For better visualization, two blunt Hohmann retractors are placed around the femoral neck. The anterior asphericity and the fibrillated cartilage in the area of impingement are visible. F. Intraoperative view of a left acetabulum. A labral ganglion extending into the soft tissues is visible at the anterosuperior acetabular rim, and the anterosuperior acetabular cartilage flap is seen.

**INTRA-ARTICULAR SURGERY FOR FEMOROACETABULAR IMPINGEMENT**

**Site Assessment**
- Before the hip is dislocated, the presence and amount of effusion and synovitis are noted.
- The head-neck junction is observed for the presence of a nonspherical extension (TECH FIG 4).
- The site of femoroacetabular impingement is evaluated by flexion-internal rotation movements.
- The femoral head is dislocated anteriorly, making it possible to fully evaluate the femoral head-neck junction as well as the acetabulum.
Acetabular version is assessed and compared with the preoperative radiographs.
- With a blunt probe, the integrity of the labrum and the articular cartilage is determined, and the quality and quantity of any damage or injury is documented.

**Acetabular Rim Trimming and Labral Refixation**
- If there is acetabular retroversion, resection of the excessive anterior rim is performed.
- The labrum is sharply detached in a bucket-handle shape and preserved for later refixation (TECH FIG 5A–C). In most instances, it can be detached at its base.

**TECH FIG 4** Inspection of the femoral head in situ. The anterior asphericity can be seen. Dynamic inspection with flexion and internal rotation shows the area of impingement.

**TECH FIG 5** A, B. Labral detachment is undertaken in a case of acetabular retroversion. C. Intraoperative view in a left hip, where the degenerate labrum has been detached from anteroinferiorly to superiorly. D, E. The acetabular rim is resected. F. Intraoperative view. G. Labral refixation using a bone anchor.
on the acetabular rim, and the degenerated labral base and the osseous overcoverage are resected.

- The amount of acetabular rim resection is determined by the magnitude of the damage to the acetabular cartilage and the degree of overcoverage.
- Resection should not be too excessive, to avoid instability of the hip.
- Resection of the excessive acetabular rim, including the area with damaged cartilage, is performed using a curved 10-mm osteotome (TECH FIG 5D–F).
- If a zone of cartilage damage persists, microfracturing is performed.

- Most acetabular rim lesions are located anterosuperiorly, close to the anterior inferior iliac spine.
- Two to four bone anchors are required to reattach the labrum.
  - Titanium anchors are smaller and fit better to the thin anterior rim.
  - Positioning of the anchors is performed under direct vision, about 2 mm from the bone–cartilage interface.
- In the case of general overcoverage (eg, coxa profunda, protrusio), circumferential detachment of the labrum and resection of the acetabular rim can be necessary.
  - In these cases, up to eight bone anchors may be necessary.
  - Nonabsorbable sutures are used to avoid potential resorption-induced inflammatory reactions.
  - Knots are tied on the outer (capsular) surface, with the suture being passed through the base of the labrum (TECH FIG 5G).

Further Femoral Preparation

- After acetabular rim trimming and labral refixation, the acetabulum is irrigated carefully to remove all bony and fibrous debris, and the retractors are removed to proceed with femoral preparation.
- The cartilage of the exposed femoral head is constantly irrigated.
- The nonspherical portion of the femoral head is assessed using transparent spherical templates (TECH FIG 6A).
  - Usually, the nonspherical part of the head–neck junction is located anterolaterally. The transition from the aspherical to the nonspherical part usually is characterized by a reddish appearance of the cartilaginous surface.
  - Excess bone is removed, and a smooth femoral neck waist is created (TECH FIG 6B,C) using small curved osteotomes.
  - Excessive bone removal during the offset procedure should be avoided, although a resection of less than 30% of the neck diameter does not weaken the femoral neck.
  - An excessive resection can compromise the sealing function of the labrum.
  - Anterior and anterolateral osteochondroplasty are relatively safe, because most terminal branches of the MFCA enter the femoral head through vascular foramina at the lateral and posterolateral head-neck junction.
  - Protecting these vessels is essential for preservation of the blood supply to the femoral head.
  - If the nonspherical portion is very lateral and posterolateral, the osteotome is advanced carefully into the cartilage or bone, aiming toward the expected entry point of the lateral retinacular arteries.
  - Before reaching that point, the osteotome is withdrawn, and the remaining bone bridge is broken off.
  - Using a knife, the bony fragment is detached subperiosteally from the inside out.
  - In this way, even very lateral and posterolateral offset alterations can be removed.
  - Perfusion of the femoral head is checked by observation of the bleeding coming from the foveolar artery or the resection surface, but laser Doppler flowmetry also may be used.
  - The hip is reduced by manual traction and internal rotation on the flexed knee.
  - Sliding of the femoral head over the area of labral refixation should be avoided, because this could avulse the sutured labrum.
  - With the head reduced, range of motion is reevaluated, and the hip is checked to determine whether flexion and internal rotation still leads to a femoroacetabular conflict.

**TECH FIG 6** • A. The sphericity of the femoral head is checked using a spherical template. When the end of the template reaches the aspheric part, or bump, it is lifted off from the cartilage. B. Femoral osteochondroplasty. C. Intraoperative view in a left hip. The lateral retinacular arteries enter the femoral head just posterior to the posterior end of the osteochondroplasty. In this case the offset deficiency is mostly anterior.
PEARLS AND PITFALLS

Blood supply to femoral head
- A thorough knowledge of the blood supply in the adult hip is mandatory to allow safe execution of surgical dislocation of the hip.
- The MFCA, the primary source of blood to the adult femoral head, arises from the deep femoral artery. The MFCA courses posteriorly between the psoas and pectineus muscles before approaching the posterior aspect of the proximal femur, running along the inferior border of the obturator externus muscle and just proximal to the quadratus femoris.
- A constant trochanteric branch separates at the level of the external obturator tendon and curves anteriorly over the greater trochanter. This vessel can be used to locate the deep branch of the MFCA, the superior border of the quadratus femoris, and the tendon of the obturator externus. The deep branch of the MFCA crosses the tendon of the obturator externus posteriorly and continues anterior to the conjoined tendon, which consists of the superior and inferior gemellus and the obturator internus tendon. Its course explains why the short external rotators must be protected. It perforates the capsule at the superior margin of the superior gemellus tendon and divides into several terminal branches, the so-called “retinacular” vessels.
- Almost 80% of all foramina are located at the posterosuperior head–neck junction. A mobile wad of loose connective and synovial tissue, the retinaculum, covers these vessels. During dislocation of the femoral head, the external rotators, especially the obturator externus, protect the MFCA from stretching or rupture. If the capsulotomy is performed strictly anterior, damage to the retinaculum can be avoided.

Nerve injury
- The sciatic nerve runs in close proximity to the piriformis muscle and is at risk when the capsular exposure is erroneously performed distal to the piriformis muscle. This is even more dangerous in the rare case of a double-branched sciatic nerve that encloses the piriformis. Under such circumstances, the insertion of the piriformis tendon at the greater trochanter should be released to avoid stretching of the branches during dislocation.
- In patients who have had previous hip surgery, the sciatic nerve may be entrapped within scar tissue. This again places the nerve at higher risk for traction injury during dislocation. In such a condition the nerve is preferably identified and released from scar tissue before continuing with the procedure.

CLOSURE
- A running suture or single stitches can be used to close the capsule.
- It is important to avoid any tension, because this may stretch the retinaculum and adversely influence perfusion of the femoral head.
- The trochanteric fragment is anatomically reduced and fixed with two or three 3.5-mm cortical screws (TECH FIG 7).
- Screw heads are countersunk to avoid irritation of the fascia lata.
- Thereafter, the various soft tissue layers are closed by running or single-stitch sutures.
- Drains rarely are used, because there is almost no dead space left behind where drainage could be advantageous.
- In women, meticulous fascial closure and subcutaneous tissue adaptation is performed, to prevent saddlebag deformity.
The safe zone to perform osteochondroplasty is anterior and anterolateral. If the resection must be extended more laterally, it is necessary to stay proximal to the retinacular vessels to avoid avascular necrosis of the femoral head.

The risk of avascular necrosis of the femoral head is high if the osteotomy is too medial and extends into the base of the neck. Therefore, the posterosuperior edge of the greater trochanter should be identified before the trochanteric osteotomy is performed, and it is of paramount importance that the osteotomy exit anterior to the posterosuperior edge of the greater trochanter.

To reduce the risk of avascular lesions of the femoral head cartilage or acetabular labrum, the straight lateral incision is preferred in obese or female patients to avoid development of a saddlebag deformity. A longer incision may facilitate surgical exposure of the hip, helps to protect the muscle fibers, and allows for easy dislocation of the femoral head with unlimited view.

The Kocher-Langenbeck approach has one advantage over the Gibson approach: it allows better inspection of the posterior aspect of the femoral head and neck, especially in obese patients.

Aiming for short incisions might be dangerous, because they may cause soft tissue damage to the skin and musculature due to stretching.

Postoperative rehabilitation includes touch-down weight bearing for 6 weeks until solid union of the trochanteric osteotomy is achieved.

During the same period, the patient receives low-molecular-weight heparin to prevent deep venous thrombosis.

Flexion of more than 90 degrees and active abduction or flexion of the hip are restricted to allow proper healing of the trochanteric osteotomy.

Continuous passive motion (CPM) with flexion allowed to 90 degrees is started the day after surgery to prevent articular adhesions between the femoral osteochondroplasty and the capsule. Prolonged use of CPM depends on whether or not microfracturing for acetabular cartilage damage was necessary. In such a case, CPM may be necessary for 6 to 8 weeks.

Appropriate patient selection is the key for a good result.

Hips with osteoarthritis higher than grade I on the Tönnis classification have a high risk of an unsatisfactory to poor result.

In a first study we reported good to excellent outcomes in 75% of patients.

In 5 patients (25%), conversion to total hip replacement was necessary, because four of those hips had advanced stage osteoarthritis or large chondral defects on the femoral head.

In a clinical survey including 277 patients, an overall improvement was achieved in 70% of the patients.

Statistical analysis revealed good outcome in hips without radiographically visible degenerative changes and good pre-operative hip function.

Ectopic ossification

Non-union of the greater trochanter

Infection

Deep vein thrombosis

Ischial nerve palsy (anatomical variants, previous surgery)

DEFINITION
- Anterior femoroacetabular impingement encompasses a category of structural hip disorders that are characterized by abnormal abutment of the anterolateral femoral head–neck junction against the acetabular rim–labral complex.
- Repetitive anterolateral impingement produces acetabular articular cartilage delamination, labral disease, and, eventually, secondary osteoarthritis.

ANATOMY
- Understanding the pathoanatomy of hip impingement disorders is essential to establishing an accurate diagnosis and selecting an optimal surgical treatment strategy.
- Structural impingement disease can be primarily femoral-based (ie, “cam” impingement) or primarily acetabular-based (ie, “pincer” impingement) (FIG 1).²,¹²,¹⁷
  - Combined cam and pincer impingement deformities are common,² and are characterized by abnormal anatomy of both the proximal femur and the acetabulum.
  - Deformities of the proximal femur that produce impingement disease include reduced femoral head–neck offset, an aspherical femoral head, slipped capital femoral epiphysis, Perthes abnormalities, and femoral neck malunion.
  - The common impingement deformities on the acetabular side include acetabular retroversion, coxa profunda, and protrusio acetabulum.

PATHOGENESIS
- Impingement deformities of the proximal femur or acetabulum, or both, produce an abnormal mechanical environment that initiates and sustains hip joint degeneration.¹²,¹⁷,²²
  - Mechanical impingement is most pronounced with hip flexion alone or hip flexion and combined internal rotation.
  - Recurrent impingement of the anterolateral femoral head–neck junction with the acetabular rim–labral complex initiates a detrimental cascade of biologic events.
  - Osseous impingement leads variably to delamination of the articular cartilage of the acetabular rim, labral degeneration, posteroinferior acetabular articular disease (due to levering of the femoral head from anterior impingement), and anterolateral femoral head–neck junction chondral disease.
  - This constellation of intra-articular disease worsens with time and is a common cause of secondary osteoarthritis.¹²,¹⁷,²²

NATURAL HISTORY
- The natural history of anterior femoroacetabular impingement has not been clearly defined.
- Radiographic studies have demonstrated an association between structural impingement deformities and secondary osteoarthritis,¹¹⁵,²² but authentic natural history data are lacking.
- The consensus is that the prognosis of symptomatic impingement disorders is poor, and that these diseases commonly result in secondary osteoarthritis.
- Future natural history studies will add substantially to improved understanding of these disorders.

PATIENT HISTORY AND PHYSICAL FINDINGS
- Patients with anterior femoroacetabular impingement commonly present with activity-related anterior inguinal (groin) pain. Associated lateral and posterior hip pain are common.
- Symptoms are variable and may include a combination of aching pain with intermittent episodes of sharp or stabbing pain.
**Part 3** ADULT RECONSTRUCTION • Section II HIP PRESERVATION

- Mechanical symptoms of locking and catching also may be problematic, presumably from labral disease or unstable articular cartilage flaps.
- Difficulty with daily activities, including prolonged walking, prolonged sitting, raising from a seated position, and pivoting, is common.
- High-demand athletic activities, including running, cutting, pivoting, and repetitive hip flexion (eg, soccer), often exacerbate symptoms.
- Any history of hip trauma, childhood hip disease, previous surgeries, and previous treatments should be determined.
- The patient’s age, activity level, and overall health, and the impact of hip dysfunction on his or her quality of life are obtained.
- Physical examination should include assessment of overall health, conditioning, and body habitus.
- Previous surgical scars are inspected to clarify the nature of previous procedures and to facilitate preoperative planning.
- Observation of sitting posture, gait, palpation of the hip, abductor strength testing, careful hip range of motion assessment, and specific provocative tests are performed.
- Anterior femoroacetabular impingement commonly elicits discomfort in an erect sitting position.
- A level pelvis in the single-legged stance is normal. Dropping of the contralateral hemipelvis indicates abductor weakness of the symptomatic hip. Abductor weakness is common in patients with early intra-articular hip disease and impingement.
- Hip flexion commonly is restricted to 100 degrees or less in impingement disorders. Internal rotation in flexion is frequently restricted to 0 to 10 degrees.
- The gait pattern over short distances and abductor strength usually are normal in early stages of disease.
- A limp and mild abductor weakness may develop as labral disease and joint degeneration progress.
- Hip range-of-motion testing should be performed carefully with stabilization of the pelvis to accurately define motion endpoints. Passive hip flexion motion and internal rotation at 90 degrees of flexion are restricted. Hip discomfort often is reproduced at the endpoints of passive motion.
- The anterior impingement test and Patrick’s test are sensitive maneuvers to detect intrinsic hip disease and usually reproduce hip symptoms in patients with anterior femoroacetabular impingement.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Plain radiographs include a supine anteroposterior (AP) view of the pelvis, cross-table lateral view with the extremity in 15 degrees of internal rotation, and a frog-leg lateral view.
- The structural parameters of the hip are assessed on all radiographic views.
- The acetabular inclination, femoral head coverage, and acetabular version are determined from the AP view of the pelvis. Joint space narrowing, periarticular cysts, and labral ossification also are noted.
- The lateral views are examined to assess femoral head sphericity and femoral head–neck offset.
- These projections best visualize the anterior and anterolateral femoral head–neck deformity that characterizes cam impingement disease.

---

**FIG 2** Radiographic assessment of acetabular version. A. Drawing of an AP view of the hemipelvis showing a hip with normal version. Note the near parallel orientation of the anterior and posterior (dashed line) acetabular walls. There is no crossover, and the lines converge at the superolateral aspect of the acetabulum. B. Drawing of a hip with acetabular retroversion. The “crossover” sign, which has been previously described as an indicator of acetabular retroversion, is present. The anterior aspect of the acetabular rim projects lateral to the posterior aspect of the rim (dashed line) at the most proximal aspect of the acetabulum. C–E. Preoperative radiographs from a 19-year-old football player with left hip pain and cam impingement. C. In this case, the patient has relatively normal acetabular version, femoral head coverage, and acetabular inclination on AP view. D. On the frog-leg lateral view, an anterolateral prominence is noted at the femoral head–neck junction (arrow). E. On the cross-table lateral view, there is a mild decreased offset from the anterior aspect of the femoral head to the anterior aspect of the femoral neck (arrow). (A,B: Adapted from Espinosa N, et al. Treatment of femoro-acetabular impingement: preliminary results of labral fixation. J Bone Joint Surg Am 2006;88A:925–935.)
An MR arthrogram (MRA) of the hip is obtained on all patients with suspected impingement and associated intra-articular disease.
- The contour of the femoral head-neck junction, labral disease, and associated articular cartilage disease are all inspected.
- The MRI also facilitates exclusion of other uncommon disorders, including stress fracture, osteonecrosis of the femoral head, neoplasm, and infection.
- CT scanning of the hip can be useful in identifying and characterizing the extent of osseous impingement lesions.
- The contour of the femoral head-neck junction and the extent of femoral-sided disease can be appreciated in detail.
- Version of the acetabulum and associated osseous abnormalities of the acetabular rim also can be assessed in detail.
- The CT scan complements other imaging modalities and can impact surgical decision making.

DIFFERENTIAL DIAGNOSIS
- Isolated intra-articular hip disease (eg, synovitis, labral tear, chondral disease, loose body) in the absence of an impingement disorder
- Mild hip dysplasia (joint instability)
- Extra-articular disorders (eg, lumbar spine disease, bursitis, inguinal hernia)

NONOPERATIVE MANAGEMENT
- Nonoperative management for the treatment of anterior femoroacetabular impingement has not been rigorously investigated or documented in the literature.
- Consensus is developing that hip impingement disease is common, and that definitive treatment should address the underlying pathomechanics of the joint.
- The benefit of nonoperative treatment has not been established for joints that are relatively healthy with no or mild degenerative changes.
- Activity restrictions, physical therapy, anti-inflammatory medicines, and intra-articular cortisone injections can be considered as potential nonoperative treatment options. Nevertheless, the efficacy of these treatment modalities over time has not been proven.
- Physical therapy should not emphasize improving hip range of motion and should avoid aggressive maneuvers to gain hip flexion and internal rotation motion, because these will irritate the hip.
- Anti-inflammatory medicines may reduce discomfort derived from labral disease and structural impingement.
- Activity restriction may alleviate symptoms in some patients. Athletes involved in repetitive hip flexion activities may experience significant relief of discomfort if they refrain from their sport.
- Patients with symptomatic femoroacetabular impingement who desire to maintain high activity levels often fail nonoperative management and desire surgical intervention.
- For patients with moderate to advanced degenerative disease, the nonoperative modalities listed can be considered as temporizing therapies before joint arthroplasty.

SURGICAL MANAGEMENT
- Surgical management of hip impingement disease continues to evolve, and various surgical techniques are now available for joint reconstruction, including surgical dislocation of the hip, combined hip arthroscopy and limited open decompression, and purely arthroscopic decompression techniques. The fundamental goal of surgery, independent of the technique selected, is to address the structural impingement lesions and the associated intra-articular disease elements (eg, labrum, articular cartilage).
- We prefer surgical dislocation of the hip for cases with nonfocal impingement problems or severe deformities and for those cases requiring acetabular rim trimming with labral repair, eg, hips with a nonfocal femoral head deformity or circumferential pincer impingement.
- For hips with focal, cam-type anterior femoroacetabular impingement, the less-invasive surgical techniques may have distinct advantages. In such cases, we use hip arthroscopy to precisely address the intra-articular disease (eg, labrum, articular cartilage), followed by a limited open osteochondroplasty to correct the femoral-sided impingement deformity.

Preoperative Planning
- The patient history and physical examination findings are reviewed.
- All preoperative radiographs plus the MRA and CT scan (if obtained) are evaluated. The size and location of the impingement lesion or lesions is determined. The status of the acetabular labrum and articular cartilage should be assessed on the MRA.
- Restriction of hip flexion motion and internal rotation in flexion is noted, because these clinical parameters should be improved with recontouring of the anterolateral femoral head-neck junction.
- It is very important that the surgeon determine whether the impingement lesion is a cam, pincer, or a combined cam-pincer deformity, because the characteristics of the specific deformity will impact the surgical planning and treatment.
- In our practice, hip arthroscopy and limited open osteochondroplasty of the femoral head-neck junction are used primarily for the treatment of cam-type impingement and associated intra-articular disease.

Positioning
- Spinal or general anesthesia with muscle relaxation is preferred.
- The patient is positioned supine on a radiolucent fracture table with lower-extremity traction attachments (FIG 3). The feet and ankles are well padded and firmly stabilized within the traction boots. The perineal post is heavily padded to prevent pudendal nerve palsy.

FIG 3 • Surgical positioning and operating room set-up. The patient is positioned supine on a radiolucent fracture table. The hip arthroscopy is performed first followed by the limited open osteochondroplasty of the femoral head-neck junction.
The operative hip initially is positioned in neutral flexion-extension and slight (0 to 10 degrees) abduction. The operative lower extremity is internally rotated 15 to 20 degrees.

The contralateral hip is flexed about 15 degrees and abductd 10 to 20 degrees, and minor traction is applied to stabilize the pelvis.

The ipsilateral upper extremity is positioned over the chest.

Traction is applied to the operative hip to achieve 8 to 10 mm of joint distraction, which is confirmed with fluoroscopy. Traction is released during preparation and draping of the hip.

**HIP ARTHROSCOPY PORTALS**

- Hip arthroscopy is performed via the anterior, anterolateral, and posterolateral portals with the patient in the supine position ([TECH FIG 1A](#)). The limited open osteochondroplasty of the femoral head-neck junction also is performed in the supine position. This surgical incision uses the Smith-Peterson interval to access the anterior hip joint.[19]

- The open incision is 8 to 10 cm long and extends from the anterosuperior iliac spine distally to incorporate the anterior arthroscopic portal ([TECH FIG 1B](#)).

- A cannulated hip arthroscopy system is used for portal placement.

- The anterolateral portal is established first with fluoroscopic guidance.

- The joint is entered distal to the labrum and superior to the femoral head. A 70-degree arthroscopic lens is inserted and used to directly visualize placement of the anterior and posterolateral portals ([TECH FIG 1C,D](#)).

- The anterior portal should be established with specific care to avoid injury to the lateral femoral cutaneous nerve.

- A superficial skin incision is made, and the soft tissues are then spread with a hemostat down to the hip capsule.

- The cannula sheath is advanced through the subcutaneous tissue to the hip capsule, and the trocar is advanced into the joint.

- Diagnostic evaluation of the central compartment is performed with both a 70- and 30-degree arthroscope. This enables excellent visualization of the femoral head and acetabulum.

- Most arthroscopy is done with the arthroscope in the anterolateral portal, but the anterior and posterolateral portals are used for comprehensive joint inspection.

**HIP ARTHROSCOPY FOR LABRAL AND CHONDRAL DISEASE**

- The anterior and superolateral labrum is carefully inspected and probed ([TECH FIG 2A](#)).

- If a labral tear is identified, the labrum is débrided back to the stable labral remnant.

- The débridement is performed with a combination of an arthroscopic shaver and radio-frequency chisel.

- Care is taken to be conservative in not resecting excessive labral tissue.

- In most cases, the capsular attachment of the labrum remains stable and should not be excised.

- Labral repair is an option in selected cases, but our initial experience has focused on partial labral resection ([TECH FIG 2B](#)).

- The articular cartilage is assessed, specifically along the anterior and superolateral rim of the acetabulum.

- Unstable flaps of articular cartilage should be removed with a mechanical shaver.

- If full-thickness delaminated flaps are present, they are débrided back to a stable articular cartilage remnant ([TECH FIG 2C](#)). Care is taken to avoid
Central propagation of the delaminated articular flaps.

- When subchondral bone is exposed, microfracture treatment is performed (TECH FIG 2D,E).
- Associated synovitis is ablated.
- When arthroscopic evaluation and treatment of intra-articular disease is completed, the instruments are removed and the traction is released.

**LIMITED OPEN OSTEOCHONDROPLASTY**

**Surgical Approach**

- The patient is maintained in a supine position and an 8- to 10-cm incision is made extending from the lateral aspect of the anterior superior iliac spine distally to incorporate the anterior arthroscopic portal incision (TECH FIG 3A).
- The dissection is carried through the subcutaneous tissue to the fascia of the tensor fascia lata muscle (TECH FIG 3B). Care is taken to bring the subcutaneous dissection slightly lateral to avoid the lateral femoral cutaneous nerve.
- The fascia of the tensor muscle is incised over the muscle belly, and the tensor fascia muscle is reflected laterally. The medial soft tissue flap, including the sartorius, is reflected medially. The underlying rectus tendon is identified.
- The direct and indirect heads of the rectus are released and reflected distally to allow wide access to the hip and wide exposure of the femoral head-neck junction (TECH FIG 3C,D).

**TECH FIG 2** Arthroscopic treatment of intra-articular disease. A. The anterior and superolateral labrum are inspected and probed. Labral disease commonly involves this region of the acetabular rim and often includes a degenerative, intra-articular tear with an intact capsular attachment. B. Partial labral resection is performed, and the adjacent articular cartilage is examined. C–E. Unstable articular cartilage flaps are débrided (C), and exposed subchondral bone is treated with a microfracture technique (D,E).

**TECH FIG 3** Osteochondroplasty surgical approach. A. The anterior incision (8–10 cm) is started at the lateral aspect of the anterosuperior spine and extended distally to incorporate the anterior arthroscopic portal incision. B. The dissection is carried through the subcutaneous tissue to the underlying fascia of the tensor fascia lata (TFL) muscle. The fascia is incised, and the tensor muscle belly is reflected laterally. The sartorius is reflected medially. C. This enables exposure of the direct (pictured) and indirect heads of the rectus femoris tendon. D. Both heads of the rectus tendon are released, exposing the underlying iliocapsularis muscle over the anterior hip joint capsule. The iliocapsularis is reflected distally and medially. The plane between the hip capsule and overlying iliopsoas muscle is developed medially. (continued)
After release of the rectus, the soft tissue and iliocapsularis muscle fibers are stripped from the anterior hip capsule. A cobra retractor is placed medially between the psoas muscle and the anterior hip capsule, and a right angle narrow-deep retractor is placed laterally.

A capital "I"-shaped arthrotomy is made, and the retractors are moved intra-articularly to displace the medial and lateral capsular flaps and provide access to the femoral head and neck (TECH FIG 3E,F).

The foot is then removed from traction and positioned on the radiolucent table to allow unrestricted motion of the lower extremity and wide access to the femoral head–neck junction.

The joint is inspected with specific attention to the femoral head–neck junction.

**Femoral Head–Neck Recontouring**

The lower extremity is brought up into a figure 4 position, which enables excellent visualization of the anteromedial head–neck junction.

- This region of the proximal femur commonly has normal offset in the face of reduced anterolateral head–neck junction offset. Thus, the anteromedial neck contour may be used as a template for the anterolateral osteochondral resection.

- Articular cartilage discoloration, the presence of chondromalacia, or evidence of an impingement trough (indentation) also is observed at the anterolateral femoral head–neck junction (TECH FIG 4A). The osteochondroplasty is started proximal to the area of suspected impingement.

- A combination of ½- and ¼-inch curved osteotomes is used to perform the recontouring of the femoral head and neck (TECH FIG 4B). The osteochondroplasty is beveled inferiorly to prevent delamination of the preserved femoral head articular cartilage.

- The depth of the osteochondroplasty ranges from 5 to 10 mm, depending on the severity of the deformity. The resection usually involves the majority of the anterolateral femoral head–neck junction, and may expand to cover more than 180 degrees of the femoral head–neck circumference.

- Lower extremity positioning with internal and external rotation greatly enhances the extent of visualization and allows safe recontouring under direct vision.

- Care is taken not to extend into the posterolateral femoral neck, because this area contains the terminal branches of the deep branch of the medial femoral circumflex artery.

- After the femoral head has been recontoured, the resection is assessed by direct visualization and palpation through the arthrotomy. Anterior femoroacetabular impingement is examined dynamically by palpation through the arthrotomy while moving the hip into flexion and combined flexion–internal rotation.

- If palpation identifies residual impingement, then the resection is refined to remove the impinging structures at the femoral head–neck junction or the femoral neck.

**TECH FIG 3 • (continued)**

E. The anterior hip capsule is then identified and a capital I-type arthrotomy made. F. The retractors are placed intra-articularly, and exposure of the anterolateral head–neck junction is obtained.

**TECH FIG 4 •** Femoral head–neck recontouring. The anterolateral femoral head–neck junction is inspected. A. Care is taken to observe any irregularity in the articular cartilage, discoloration of the articular cartilage, and impingement trough or indentation. B. The osteochondroplasty and recontouring of the anterolateral femoral head–neck junction are performed using ½- and ¼-inch curved osteotomes. C. After the osteochondroplasty is completed and inspected by direct physical examination and fluoroscopy, the osteochondroplasty bony bed is treated with bone wax.
Fluoroscopic examination is performed after completion of femoral head recontouring to confirm sphericity and adequate osteochondral resection. The head is visualized in extension with neutral rotation and external rotation. The hip is then examined in a frog-leg lateral position to better visualize the anterolateral head–neck junction. Varying degrees of flexion and internal–external rotation permit excellent assessment of the osteochondroplasty.

The recontouring of the femoral head–neck junction is complete, the osteochondroplasty bed is treated with bone wax (TECH FIG 4C).

TECH FIG 5 • The hip joint capsule and overlying rectus tendons are repaired.

## PEARLS AND PITFALLS

### Indications
- Ideal surgical candidates have symptomatic anterior femoroacetabular impingement, are well-conditioned, are less than 55 years old, and have no or mild secondary osteoarthritis.
- The patient history and physical examination are extremely important to make a definitive diagnosis of anterior femoroacetabular impingement.
- The radiographic and imaging studies are critical in classifying the type of impingement disease.
- Various surgical options are available to treat hip impingement disease.
- The surgical strategy presented here has been used primarily for the treatment of cam-type deformities.

### Labral débridement
- It is extremely important to be technically conservative with the partial labral resection.
- Unstable intra-articular flaps of the labrum should be removed.
- The stable capsular labral remnant should be preserved when possible.
- Full-thickness resection of the labrum should be avoided.

### Articular cartilage
- Articular cartilage delamination along the anterior and superolateral acetabular rim is common.
- Articular flaps should be débrided back to stable articular cartilage.
- Microfracture of the acetabular rim disease can be performed for full-thickness defects.

### Limited open osteochondroplasty
- Wide exposure of the femoral head–neck junction should be obtained to perform the osteochondroplasty safely and precisely.
- Exposure is best achieved by release of the rectus tendon and an I-shaped arthrotomy to enable wide access to the anterolateral head–neck junction.
- A combination of 1/4- and 1/2-inch angled and curved osteotomes facilitates the osteochondroplasty through this surgical approach.
- Dynamic examination of the hip and palpation through the arthrotomy ensures complete decompression of the impinging structures.
- Fluoroscopic examination of the hip after osteochondroplasty assists in judging the adequacy of the femoral head–neck junction recontouring.

### Postoperative rehabilitation
- Emphasis should be on gentle range of motion within the patient's comfort zone and gentle, progressive strengthening as tolerated by the patient.
- A common mistake is excessive therapy within the first 2 months after surgery. This can impede the rehabilitation process.
POSTOPERATIVE CARE

- Postoperative radiographs are obtained to verify the contouring of the femoral head–neck junction and to document the integrity of the proximal femur (FIG 4).
- Patients are treated with one aspirin two times a day for 6 weeks for deep venous thrombosis prophylaxis, and with indomethacin, 75 mg per day for 6 weeks, to prevent heterotopic ossification.
- Patients are toe-touch weight bearing for 4 weeks and then progress to full weight bearing. Gentle physical therapy is started the day after surgery. Therapy focuses on gentle range of motion and progressive strengthening within the patient’s comfort zone.
- Continuous passive motion is used for 4 to 6 hours per day for 2 to 4 weeks.
- The patient may return to normal daily activities as tolerated 4 weeks after surgery and may return to contact sports or running 6 months after surgery.

OUTCOMES

- Documentation of clinical outcomes for surgical treatment of hip impingement disease is limited.3,8,10,14,21
- Early to mid-term results are now available for treatment with surgical dislocation of the hip and are encouraging for most patients.3,10,21
- Reported clinical outcomes with less invasive impingement techniques are limited.8,14
- Our experience with hip arthroscopy and combined limited open osteochondroplasty has been encouraging. Analysis of our first 23 consecutive cases demonstrated good or excellent clinical results in 22 of the 23 hips at a mean 18 months of follow-up.8

COMPLICATIONS

- Femoral neck fracture
- Infection
- Articular cartilage scuffing
- Arthroscopic instrument breakage

REFERENCES

DEFINITION
- The knee classically has been divided into three compartments. Unicondylar knee arthroplasty (UKA) is performed for medial or lateral compartment arthritis.
- Historically, patient selection, surgical technique, and component designs have been less than ideal. The key to a successful outcome for UKA is a successful marriage between these three variables.

ANATOMY
- The three compartments of the knee are the lateral compartment, consisting of the lateral tibial plateau and lateral femoral condyle; the medial compartment, made up of the medial tibial plateau and medial femoral condyle; and the patellofemoral joint.
- In the normal knee, most of the ligaments are at their resting, unstretched lengths in extension.
  - At about 20 to 30 degrees of flexion, the posterior capsule and lateral collateral ligament (LCL) slacken, allowing for a gap under tension.
  - Further gapping is resisted by the anterior cruciate ligament (ACL), posterior cruciate ligament (PCL), and medial collateral ligament (MCL).
  - At 90 degrees of flexion, the lateral compartment will distract 7 mm while the medial compartment maintains a constant 2-mm gap.
  - The cruciate ligaments and the MCL exert an isometric effect on the medial compartment throughout the range of motion.
  - In a single-leg stance, the load across the medial compartment is approximately 70%. This increases to 90% when there is a varus deformity of 4 to 6 degrees.

PATHOGENESIS
- Medial unicompartmental osteoarthritis (OA) with intact cruciate ligaments and a functionally normal MCL results in a recognizable pattern of wear.
  - Cartilage and bone erosions are found on the anteromedial tibial plateau and distal surface of the femur, representing a pattern of extension disease.
  - Erosions rarely extend to the posterior quarter and never to the posterior joint margin of the tibial plateau.
  - Cartilage is preserved on the flexion surface of the femur and posterior tibia.
  - The intact ligaments maintain normal femoral “rollback,” resulting in this typical pattern of wear.
  - With a varus deformity, the posterior capsule shortens. However, when the capsule is relaxed at 20 degrees of flexion, the knee can be corrected manually to its prediseased alignment.
  - At 90 degrees of flexion, the knee corrects spontaneously as the cartilage on the flexion surface of the femur comes in contact with the posterior tibia.
- The MCL subsequently is tensioned to its normal length in flexion.
- Unlike tricompartmental disease, unicompartmental disease should not require any ligamentous release during arthroplasty.
- To expose bone on both the tibia and femur, almost 5 mm of cartilage is lost. This typically causes 5 degrees of varus deformity.
- Each additional millimeter of bone lost will result in increasing varus deformity of 1 degree.

NATURAL HISTORY
- Degenerative failure of the ACL may be the event that causes anteromedial OA to make the transition to posteromedial OA, resulting in posterior subluxation and structural shortening of the MCL.
- Varus deformity also will be maintained in flexion as the posterior cartilage is worn.
- The ACL progresses through these stages of failure: normal, loss of synovial covering (usually distal), longitudinal splits in the exposed tendon, stretching and loss of strength, and, finally, rupture, with eventual disappearance of the ligament.
- Chronic synovitis causes nutritional insufficiency and will place the ACL at risk.
- Intercondylar osteophytes from arthritis also will put the ACL at risk of degenerative changes and failure.

PATIENT HISTORY AND PHYSICAL FINDINGS
- Pain is the most common symptom of OA.
  - Pain usually is recognized along the medial joint line, but its localization is unreliable.
  - Pain is felt on standing and walking but usually is absent with sitting or lying down.
  - Varus deformity of 5 to 15 degrees while standing is seen. The deformity corrects with 90 degrees of flexion and upon valgus stress at 20 degrees of flexion.
  - Flexion contracture often is present, as are a joint effusion and synovial swelling.
  - The Lachman’s, pivot shift, and drawer tests often are difficult to interpret in assessing the cruciate ligaments in an arthritic knee, but ligamentous stability should be present.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- Plain radiographs, including a weight-bearing anteroposterior (AP) and lateral (Fig 1A,B), stress, and patellar views, are critical in determining whether the patient is an appropriate candidate for UKA.
- If only medial compartment arthritis (ie, joint space narrowing, sclerosis, cysts, osteophytes) is appreciated on the AP view, a valgus stress view (Fig 1C) is needed.
This will demonstrate the normal thickness of the cartilage in the lateral compartment and show whether the varus deformity is correctable.

- The lateral compartment should not measure less than 5 mm (the sum of the thickness of the normal cartilage), and the medial compartment should gap at least 5 mm (the sum of the articular cartilage lost).
- Incomplete loss of medial joint space must be investigated further with a varus stress view to show complete joint space loss.
- If the joint space loss is not full-thickness, UKA should be avoided and other causes for the pain should be sought.
- Lateral radiographs reveal the extent of posterior wear and are, therefore, a reliable indicator of the functional integrity of the ACL.
- The femoral condyles and tibial plateau should appear superimposed.
- If a concave erosion is present on the anterior two thirds of the plateau, the ACL is intact (95% probability).

**DIFFERENTIAL DIAGNOSIS**

- Tricompartmental OA
- Meniscal tear
- Saphenous neuritis
- Osteochondral injury
- Pes anserine bursitis
- Septic arthritis

**NONOPERATIVE MANAGEMENT**

- Nonoperative management consists of nonsteroidal anti-inflammatory drugs, glucosamine and chondroitin, physical therapy, assistive devices, viscosupplementation, bracing, or intra-articular corticosteroid injections.

**SURGICAL MANAGEMENT**

- The patient’s suitability for UKA ultimately is decided in the operating room. The patient must have been prepared in advance for a possible conversion to a total knee arthroplasty if not all the criteria are met.
- We use the Oxford criteria, as follows:
  - Physical signs must include pain severe enough to justify joint replacement and flexion deformity less than 15 degrees.
  - Radiographic signs include full-thickness cartilage loss with eburnated bone-on-bone contact in the medial compartment; full-thickness cartilage preservation in the lateral compartment; intact articular surface at the back of the tibial plateau; and manually correctable varus deformity.
  - Intraoperative signs include the presence of an intact ACL and satisfactory appearance of the central articular cartilage of the lateral compartment.
  - Traditional contraindications for UKA include:
    - Inflammatory arthritis
    - A flexion contracture of 5 or more degrees
    - A preoperative arc of motion of less than 90 degrees
    - Angular deformity of more than 15 degrees
    - Significant cartilaginous damage in the opposite compartment
    - ACL deficiency
    - Body mass index higher than 32
    - Exposed subchondral bone beneath the patella
  - Criteria that are not considered contraindications are age, activity level, weight, patellofemoral arthritis, degenerative lateral meniscus, and chondrocalcinosis.

**Preoperative Planning**

- Preoperative templating for the appropriately sized components is performed using the lateral radiograph.
Examination is performed under anesthesia to assess the stability and motion of the knee.

**Positioning**
- A thigh tourniquet is applied and the leg is placed in a hanging leg holder (**FIG 2**).
- The hip is flexed to about 30 degrees, and the leg is abducted.
- The knee must be free to flex to at least 135 degrees.

**Approach**
- An abbreviated medial parapatellar approach is used for a medial UKA (**FIG 3**).

---

**EXPOSURE**

- With the knee flexed to 90 degrees, a medial parapatellar skin incision is made from the medial margin of the patella to a point 3 cm distal to the joint line. The capsular incision is extended obliquely and medially for 1 to 2 cm into the vastus medialis.
- Part of the retropatellar fat pad is excised, and the anterior cruciate ligament is inspected to ascertain that it is intact (**TECH FIG 1A**).
- All osteophytes must be removed from the medial margin of the medial femoral condyle and from both margins of the intercondylar notch (**TECH FIG 1B**).

**TIBIAL RESECTION**

- The front of the tibia is exposed in the lower part of the wound from the tibial tubercle to the rim of the plateau.
- As much of the medial meniscus is excised as possible.
- None of the fibers of the medial collateral ligament are released.
- The tibial saw guide is applied with its shaft parallel with the long axis of the tibia in both planes (**TECH FIG 2A**).
- The level of resection is estimated—this level varies according to the depth of tibial erosion.
- A minimum of 6 mm of intact posterior cartilage and bone should be removed.
- The saw cut should pass 2 or 3 mm below the deepest part of the erosion.
- It is better to be conservative with the first cut, because the tibia can easily be re-cut if too little bone has been removed (**TECH FIG 2B**).
TECHNIQUES

- A reciprocating saw with a stiff narrow blade is used to make the vertical tibial cut.
  - The blade is pushed into the intercondylar notch close to the lateral margin of the medial femoral condyle.
  - The blade is pointed toward the head of the femur (TECH FIG 2C).
- Before the horizontal cut is made, a retractor is inserted to protect the medial collateral ligament.
- A 12-mm-wide oscillating saw blade is used to excise the tibial plateau (TECH FIG 2D).
- The blade must go right to the back of the joint.
- When the plateau is loose, it is levered up with a broad osteotome and removed.
- The posterior horn of the medial meniscus can now be removed.
- The excised plateau will demonstrate the classic lesion of anteromedial OA and preserved cartilage posteriorly.
- The excised plateau together with the tibial templates is used to choose the size of the tibial implant.
- Sufficient thickness of bone must be removed from the tibia to accommodate the tibial template and a bearing at least 4 mm thick (TECH FIG 3A–C).
  - Whenever a feeler gauge is used to measure a gap, the retractors are removed.
  - If the retractors are left in, they have the effect of tightening the soft tissues, artificially diminishing the gap.
  - If the 4-mm gauge cannot be inserted or feels tight, then more bone needs to be excised from the tibia.
  - With the knee in about 45 degrees of flexion, a hole is made into the intramedullary canal of the femur with the awl. The hole must be situated 1 cm anterior to the anteromedial corner of the intercondylar notch.
- The knee is then flexed to 90 degrees. This must be done with care, because the medial border of the patella abuts against the rod.
  - The tibial template is replaced, the femoral drill guide is inserted, and a feeler gauge is placed that is 1 mm thinner than the flexion space between them.
  - If the gauge is too loose, a thicker gauge is inserted.
  - The femoral drill guide is now manipulated until it is in the middle of the condyle and its handle is aligned parallel with the long axis of the tibia.
- The knee is then flexed to 90 degrees. This must be done with care, because the medial border of the patella abuts against the rod.
  - The tibial template is replaced, the femoral drill guide is inserted, and a feeler gauge is placed that is 1 mm thinner than the flexion space between them.
  - If the gauge is too loose, a thicker gauge is inserted.
  - The femoral drill guide is now manipulated until it is in the middle of the condyle and its handle is aligned parallel with the long axis of the tibia.
  - By adjusting the degree of flexion of the knee, the upper surface of the drill guide is made to lie parallel with the intramedullary rod when viewed from the side.

TECH FIG 2 • A. The tibial alignment guide is placed parallel to the tibia in both the AP and lateral planes. B. With the tibial alignment guide in place, it is possible to observe the depth of tibial bone to be resected. C. A reciprocating saw is used to make the vertical tibial cut. D. A 12-mm-wide oscillating saw is used to excise the tibial plateau.
TECH FIG 3 • A. The resected fragment of tibial bone demonstrates anteromedial osteoarthritis and intact posterior cartilage. B. Tibial sizing templates are aligned on the resected tibial fragment to determine appropriate component size. C. Retractors are removed and a no. 4 feeler gauge is inserted to measure the gap between femur and tibia. D–F. With the tibial template and a feeler gauge 1 mm thinner than the flexion gap in place, the femoral drill guide is inserted and positioned to determine femoral alignment. When all alignment requirements are fulfilled, holes are drilled.

- By internally and externally rotating the tibia, the lateral surface of the fin is made to lie parallel with the intramedullary rod when viewed from above (TECH FIG 3D).
- When all of these five requirements are fulfilled, the drill is passed through the upper hole to its stop and left in place.
- The other hole is then drilled, and both drills and all instruments are removed from the joint.
- The intramedullary rod also may be removed (TECH FIG 3E,F).

POSTERIOR CONDYLE RESECTION AND MILLING

- The femoral saw block is inserted into the drilled holes.
- Using the 12-mm broad sagittal saw, the posterior facet of the femoral condyle is excised (TECH FIG 4A).
- The saw block is removed, and the 0 spigot is inserted into the large drill hole (TECH FIG 4B).
- The spherical cutter is then used to mill the distal femur until the cutter will not advance further (TECH FIG 4C).
- With the leg in 90 degrees of flexion, the tibial template is inserted and the femoral trial component is applied to the milled condyle (TECH FIG 4D).
The extension gap is measured with the knee in 20 degrees of flexion using metal feeler gauges.

**BALANCING THE FLEXION AND EXTENSION GAPS**

- The flexion gap is now carefully measured with feeler gauges. The feeler gauge will slide in and out easily but will not tilt.
- The gauge is removed. It is important to remove the gauge before extending the knee because, at this stage, the extension gap is always narrower than the flexion gap.
  - If the gauge is left in place, it may stretch or rupture the ligaments as the knee extends.
  - Next, the extension gap is measured in 20 degrees of flexion with the metal feeler gauges (**TECH FIG 5**).
  - In full extension, the posterior capsule is tight, and its influence gives a false under-measurement.
• The formula for balancing the flexion and extension gaps is as follows:
  - Flexion gap (mm) – extension gap (mm) = thickness of bone to be milled from femur (mm) = spigot number to be used.
  - For instance, if the flexion gap measures 5 mm and the extension gap 2 mm, the amount of bone to be milled is 3 mm. To achieve this, a number 3 spigot is inserted and the bone is milled until the cutter will advance no further.
• With the tibial template and the femoral trial component in place, the flexion and extension gaps are re-measured.

**TRIAL COMPONENT AND TRIAL BEARING**

• The tibial trial component is inserted and tapped home with the tibial impactor.
  - The trial component must be flush to the bone, and its posterior margin must extend to the back of the tibia.
  - Only a light hammer should be used, to avoid the risk of plateau fracture.
• Final preparation of the femur requires trimming of the condyle anteriorly and posteriorly to reduce the risk of impingement of bone against the bearing in full extension and full flexion (TECH FIG 6A).
• The femoral posterior trimming guide is applied to the condyle, and the osteophyte chisel is used to remove any posterior osteophytes.
• A trial meniscal bearing of the chosen thickness is inserted.
  - It is only at this stage that a trial bearing is used (TECH FIG 6B–D).
• Previously, feeler gauges have been used to measure the gaps, because they do not stretch the ligaments.
• With the bearing in place, the knee is manipulated through a full range of motion to demonstrate stability of the joint, security of the bearing, and absence of impingement.
• The thickness of the bearing should be such as to restore the ligaments to their natural tension so that when a valgus force is applied to the knee, the artificial joint surfaces distract a millimeter or two.
  - This test should be done with the knee in 20 degrees of flexion.
• In full extension, the bearing will be gripped firmly because of the tight posterior capsule.
INSERTING AND CEMENTING THE FINAL COMPONENT

- The femoral and tibial surfaces are roughened by multiple small drill holes made with the cement key drill (TECH FIG 7A).
- The tibial component is inserted and pressed down, first posteriorly and then anteriorly, so that excess cement is squeezed out at the front (TECH FIG 7B).
- Excess cement is removed from the margins of the component with a small curette (TECH FIG 7C).
- The femoral component is applied to the condyle and impacted with the punch held at 30 degrees to the long axis of the femur.
- Again, excess cement is removed from the margins with a small curette.
- During cement setting, the leg is held in 45 degrees of flexion (TECH FIG 7D).
- The leg should not be fully extended, because pressure in this position may tilt the tibial component anteriorly.
- The reconstruction is completed by snapping the chosen bearing into place.
- Routine closure of the wound follows.

PEARLS AND PITFALLS

<table>
<thead>
<tr>
<th>Pearls</th>
<th>Pitfalls</th>
</tr>
</thead>
<tbody>
<tr>
<td>There is a tendency to place too tight a bearing. Leave the bearing relatively loose.</td>
<td>Tibial plateau fracture must be avoided. Care should be taken not to damage the posterior cortex or cut too deep a slot for the keel. Gentle blows with a light mallet are used.</td>
</tr>
<tr>
<td>Anterior bone (4–5 mm) is removed from proximal to the femoral component to prevent bearing impingement.</td>
<td>All retractors must be removed during any trial or balance step of the procedure. Retractors will falsely tighten the gaps.</td>
</tr>
<tr>
<td>The tibial feeler gauge must be flush against the lateral rail of the tibial tray during femoral guide placement and femoral drill hole placement.</td>
<td>There is a tendency to cut too much posterior slope. The posterior slope should be about 7 degrees.</td>
</tr>
</tbody>
</table>

POSTOPERATIVE CARE

- Intraoperative local anesthetic (60 mL of 0.5% ropivacaine with 30 mg ketorolac and 0.5 mL of 1:1000 epinephrine) is injected into the damaged soft tissues.
- A drain is used; it is pulled on the first postoperative day.
- Patients typically are discharged from the hospital less than 24 hours after admission.
- Patients usually have a rapid initial recovery (FIG 4). Some patients may experience mild medial pain for 2 to 3 months after surgery.

OUTCOMES

- UKA is a predictable surgical option for appropriate candidates with anteromedial OA. Survival rate of UKA at 10 years is 90% or better (Table 1).
We performed 316 medial Oxford UKA between 2004 and 2005. Classic contraindications to UKA, such as obesity, young age, patellofemoral degenerative joint disease (DJD), and anterior knee pain, were specifically reviewed.

- Twenty-five percent of patients were obese, with BMI greater than 35.
- Fifty-four percent of patients were younger than 60 years of age.
- The incidence of radiographic patellofemoral degenerative disease was 43% preoperatively.
- Only 68% of patients reported isolated medial-sided knee pain preoperatively. Twenty-one percent described global knee pain and 6% reported anterior knee pain.
- There were no differences in failure rates or Knee Society scores between patients with preoperative anterior knee pain and those without anterior knee pain before UKA. No differences in outcomes were noted between those with and those without radiographic evidence of patellar DJD.
- No differences in outcomes were noted between obese and non-obese patients. Additionally, no differences in outcomes were seen between patients younger or older than 60 years of age.
- Our experience with the Oxford UKA now spans 2.5 years. To date, our patients have experienced five implant failures: two for tibial loosening with collapse, one for tibial plateau fracture, one for infection, and one for unexplained pain.
- There have been no dislocations of the mobile bearing.

FIG 4 • Patients typically enjoy rapid recovery, achieving high flexion with normal kinematics.

COMPLICATIONS

- Multiple series (Table 1; see also references 9 and 10) provide an overview of the potential complications and outcomes of the Oxford Mobile Bearing UKA.
- Infection has been observed in up to 0.6% of cases.
- Medial tibial plateau fracture occurs in 0.3% of cases. Care must be taken not to damage the posterior cortex.
- Retrieval studies of the Oxford UKA show wear to be 0.026 to 0.043 mm per year.
- Historically, dislocation of the mobile bearing occurs in 0.5% of cases. Primary dislocations occur for two main reasons: impingement and femoral component malposition. The bearing can impinge on posterior osteophytes or cement, causing the bearing to “spit out” anteriorly. If the femoral component is not positioned correctly, the mobile bearing can “spin out.” The newer bearing with “wings” will help resolve some spin-out issues (FIG 5). However, specific attention to placement of the femoral component is crucial.
- Progression of lateral compartment arthritis requiring revision occurred in 1.4% of patients with UKAs. Most authors believe that progression of lateral compartment OA is due to overcorrection of a varus deformity to valgus due to MCL release or damage.

FIG 5 • Although the meniscal bearing trial is universal, the actual bearing is anatomic, with longer lateral wings to enhance stability.
As many as 2% of patients may have persistent unexplained pain, possibly caused by tibial condyle overload, overhang of the tibial component, overstretching of the MCL, and pes anserine bursitis by 1 year post-surgery; most medial pain resolves spontaneously by 2 years.

REFERENCES

DEFINITION
- Upper tibial osteotomy (high tibial osteotomy [HTO]) has evolved from a procedure used strictly for treating medial compartment arthrosis of the knee to one that has implications in combination surgeries to address the entire spectrum of knee pathology.
- HTO is now used to alter the mechanical alignment of the lower extremity to offload forces through the medial compartment in arthritic knees.
- It also can be used to offload forces in cartilage restoration procedures (eg, autologous chondrocyte implantation, meniscal transplants, and osteochondral auto- and allografts).
- The subtleties of the HTO can be combined with changes in the sagittal slope of the knee to help correct or aid in treatment of anterior cruciate or posterior cruciate ligament injuries.
- Therefore, the indications for an HTO include:
  - Malalignment plus arthrosis
  - Malalignment plus instability
  - Malalignment plus instability plus arthrosis
  - Malalignment plus cartilage restoration techniques

ANATOMY
- The upper tibial location of the osteotomy has certain key anatomic points to consider for a successful result and to avoid injury to the extremity.
  - On the medial side of the knee, the pes anserine tendons insert on the anteromedial aspect of the tibia. The gracilis and semitendinosus, found on the undersurface of the sartorius fascia, must be preserved. Deep to the tendons, but composing a completely different layer, is the medial collateral ligament (MCL) (deep and superficial layers).
  - The patellar tendon insertion on the tibial tubercle and its relation to the level of the osteotomy. The osteotomy should be made proximal to the tubercle.
  - On the lateral side, the common peroneal nerve and its relation to the fibular head. The proximal tibiofibular joint also can be violated in lateral closing wedge osteotomies, leading to arthritic changes in the future.
  - The posterior neurovascular structures, including the popliteal artery and tibial nerve, must be protected during creation of the posterior aspect of the osteotomy.
  - The cross-section of the proximal tibia at the location of the osteotomy is not a cylinder, but a triangle. Therefore, the most medial location of the osteotomy is different for the posterior and anterior aspects of the tibia. Because of this, to avoid an inadvertent increase in tibial slope when opening up the osteotomy, the anterior portion of the osteotomy should be opened to one third of the posterior height (FIG 1).

PATHOGENESIS
- The biologic basis for performing an HTO can be thought of in regard to its indications.
- Arthrosis
  - Regardless of the cause of the arthritis, whether posttraumatic or primary, medial compartment arthritis continues to be exacerbated when there is mechanical overload of the medial compartment of the knee.
  - If the mechanical axis of the lower extremity from the hip-knee-ankle films shows that the weight-bearing line falls within the medial compartment, the medial cartilage is overloaded and placed at a risk for further degenerative change.
- Instability
  - Because the osteotomy can alter the orientation of the proximal tibia in two planes (coronal and sagittal), altering the slope of the tibia can aid deficient cruciate ligaments in controlling knee instability.
  - When the tibial slope is decreased, the tibia is less likely to translate posteriorly, and, therefore, the HTO can aid the patient with an anterior cruciate ligament (ACL) deficiency. When the tibial slope is increased, the tibia is less inclined to translate posteriorly, and thus the HTO can aid the patient with posterior cruciate ligament (PCL) deficiency.
  - If the status of the ACL is unknown and the tibial slope is unknowingly increased in an ACL-deficient patient, residual instability may worsen due to the biomechanical changes in knee motion.
- Cartilage restoration procedures
  - Because cartilage degeneration necessitating restorative procedures has an associated component of malalignment, placing restored or regenerated cartilage in the knee makes it necessary to off-load the involved compartment to give the new cartilage the best mechanical environment for growth and success.

NATURAL HISTORY
- The natural history of medial arthrosis with varus alignment is one of progression and further cartilage degeneration over time. The end result is a spectrum of arthritic change in the knee, from uni- to tricompartmental arthritis.
- Performing ACL reconstructions for instability on double- or triple-varus knees has been shown to have detrimental effects on the ACL graft and higher rates of failure.
- Noyes et al17 have recommended addressing both the ligament deficiency and the varus alignment of the extremity, to allow the most biomechanically secure construct and avoid excessive tension on the reconstructed graft.
- Cartilage regenerative or restorative procedures (eg, microfracture, autologous chondrocyte implantation, osteochondral auto- and allograft transplantation, meniscal transplantation) have a higher rate of failure in the setting of malalignment, because it subjects the newly implanted tissue to mechanical overload.
- Studies have shown that limb malalignment is a contraindication to these procedures if not addressed concomitantly in either a staged or concurrent fashion.1-3
PATIENT HISTORY AND PHYSICAL FINDINGS

- A thorough history should be taken to determine whether the patient’s complaints correlate with the ultimate diagnosis. This is especially important when making distinctions regarding pain from arthritis versus pain from instability and when formulating combined treatment options.
- The exact location of the pain is determined by asking the patient to point with one finger to its location.
- Medial-sided knee pain without radiation and subsequent radiographs showing medial compartment arthritis or narrowing make it possible to form a more definitive conclusion regarding surgical intervention.
- Knee pain anteriorly or laterally, for example, does not correlate with varus deformity and medial compartment arthritis, and a different diagnosis must be sought for the patient’s pain.
- Medial-sided knee pain with radiation from the hip can signify hip arthritis as the cause of the lower extremity pain.
- Radiation of the pain distal to the knee and into the foot can signify radiculopathy and a spinal cause of the lower extremity pain.
- Further classification of the pain is important, including duration and frequency of symptoms, what aggravates or alleviates the symptoms, and previous injuries to the knee in question.
- Does the patient complain of pain only, instability only, or pain plus instability? This distinction is important in the multiply injured knee with chronic ligamentous deficiency and arthritic change.
- Pain without instability and radiographs consistent with medial compartment arthritic change can be treated with an osteotomy only.
Instability only with a varus-aligned limb can be treated with a ligamentous reconstruction only when the varus is mild and there is no varus thrust. In the setting of a large varus thrust and significant varus deformity, the ligament reconstruction will fail.

Pain with instability may signify the need to include both a ligamentous reconstruction and an osteotomy, in either a staged or concurrent fashion.

Other conservative treatments have been attempted.

Medial-sided knee pain with varus alignment can respond favorably to heel wedges with lateral posts, which help to offload the medial compartment of the knee by altering the gait mechanics.

Other treatment options include medial unloader braces, which also help to alter the biomechanics of the knee by offloading the medial compartment. Heavy laborers who cannot afford to take time off of work due to job constraints often can get through the work week with the unloader braces and postpone surgical intervention.

Corticosteroid injections or viscosupplementation are other conservative treatment options for early arthritic change in the knee that can be used as temporizing measures to help relieve acute pain attacks from arthritis.

The physical examination of the varus knee should include:

- Investigation of varus thrust when assessing gait
- Collateral ligament stability as an indicator of the residual laxity of the knee in the coronal plane
- Palpation or ballottement of the patella for effusion, which indicates intra-articular cause of the symptoms
- Systematic palpation of various areas of the knee to localize pain
- Assessment of knee range of motion (ROM) to determine goals of surgery: significantly limited ROM may not be caused only by lower extremity varus alignment and may indicate advanced arthrosis.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Radiographic evaluation in planning for an HTO is of paramount importance. Routine radiographs to obtain include bilateral anteroposterior (AP) standing, bilateral posteroanterior (PA) 45-degree flexed (ie, skier’s view), lateral view of affected knee, and bilateral Merchant views.
- The AP standing and PA 45-degree flexed views allow the determination and initial grading of medial or lateral joint space narrowing. Joint space narrowing often can be found at the posterior condylar area and, therefore, may be missed on a routine AP standing knee radiograph.
  - Flexing the knee to 45 degrees allows a different area of the femoral condyle to be evaluated tangentially by the x-ray beam and may reveal significant arthritic change (FIG 2A, B).
- The lateral view allows initial assessment of the patellofemoral joint and the determination of tibial slope.
- The Merchant views complete the patellofemoral joint evaluation and assess the patellofemoral joint for arthritic changes.
- Further radiographic evaluation includes a mechanical axis view (hip-knee-ankle). This view makes it possible to determine initial varus and valgus alignment of the bilateral lower extremities and the overall mechanical axis, and to template correction angles for the opening wedge HTO (FIG 2C).
- MRI can be useful in younger patients to assess cartilage surfaces and ligament deficiency (eg, the chronic ACL-deficient knee with varus alignment and relatively preserved joint space on radiograph). The extent of cartilage surface damage can be assessed, and meniscal injuries also can be documented.
- MRI also can be useful in assessing bone marrow edema and helping to correlate the source of the patient’s pain. For example, in the varus knee with medial joint line pain, meniscal symptoms, and 4 mm of medial joint space left, it is difficult to predict whether the patient’s pain is coming directly from the meniscal tear or from early arthritic change.
- An MRI scan that shows significant bone marrow edema in the medial femoral condyle or tibial plateau indicates that a routine medial meniscectomy should be performed with caution, because the patient’s pain actually may be caused by the early arthritic changes and cartilage overload, and symptoms may increase or remain the same.
- Bone scanning can also be useful in determining the source of elusive pain in the knee (FIG 2D).

**DIFFERENTIAL DIAGNOSIS**

- Meniscal tear
- Osteochondral injury
- Bi- or tricompartmental arthritis
- ACL, PCL, posterolateral ligament instability
- Hip osteoarthritis
- Spinal pathology (eg, stenosis, disc herniation)

**NONOPERATIVE MANAGEMENT**

Nonoperative management for unicompartmental knee arthritis before an osteotomy is needed includes:

- Physical therapy and weight loss
- Medications (eg, acetaminophen, nonsteroidal anti-inflammatory drugs, glucosamine/chondroitin sulfate)
- Intra-articular knee injections: eg, corticosteroids, viscosupplementation
- Mechanical offloading devices or orthoses (eg, heel wedges with lateral posts, unloader braces). We recommend that a patient fail or find unacceptable all of these nonsurgical modalities before proceeding with an osteotomy procedure. Especially with the unloader braces, a patient may get excellent relief and can either continue the conservative treatment or decide that a formal unloading procedure, such as the HTO, would reliably relieve their pain.
- Nonoperative management for instability plus malalignment includes all of the modalities that have been discussed. However, an attempt should be made to distinguish between the patient’s complaints of pain, which may signify an underlying arthritic cause of pain, and instability, which, depending on the final alignment values, may need only a ligament reconstruction.

**SURGICAL MANAGEMENT**

Indications

- Varus malalignment with medial compartment arthritis
  - The ideal patient is physiologically young (less than 55 years old) with an active lifestyle.
  - Patients should not be excluded solely based on age. Treatment plans may focus on the current and desired
Tegner Activity Scores. No study has shown a Tegner Activity Score greater than 4 with total knee arthroplasty or unicompartmental knee arthroplasty.\textsuperscript{22}

- Varus malalignment with instability
- Posterolateral instability\textsuperscript{4,6,17}
- ACL instability

Varus malalignment with arthritis and instability

The HTO can purposely decrease tibial slope in the sagittal plane and decrease anterior translation in an ACL-deficient knee.

Conversely, the tibial slope in a PCL-deficient knee can be increased to aid in decreasing posterior tibial translation.

Varus malalignment with associated cartilage or meniscal procedures

A favorable mechanical environment for newly transplanted cartilage cells or meniscal transplantation must be created. This includes decreasing the mechanical overload in that compartment via osteotomy.\textsuperscript{7,11,14,15}

- Valgus malalignment with lateral compartment arthritis
- A distal femoral varus-producing osteotomy usually is performed to avoid producing obliquity of the tibiofemoral joint line with the varus HTO.
- Adult osteochondritis dissecans\textsuperscript{19}
- Osteonecrosis of the medial femoral condyle in physiologically young individuals

Contraindications

- Elderly patients (>60 years old) with low functional demands are better suited for a total knee replacement.
- Degeneration of the contralateral knee compartment or loss of lateral compartment meniscus
- Loss of knee motion >70 degrees
- Patellofemoral degenerative disease that is symptomatic
- Pain not consistent with clinical examination (eg, patellofemoral pain with medial compartment osteoarthritis)
- Any of the inflammatory arthritides (eg, rheumatoid arthritis)
Preoperative Planning

- All imaging studies are reviewed, especially the mechanical axis view, to determine the amount of correction needed for the osteotomy.
- The patient and surgeon should discuss the use of auto- or allograft material for bone grafting of the osteotomy site.
  - If the osteotomy is smaller than 7 degrees, typically no bone graft is needed.
  - If the osteotomy is larger than 7 degrees, bone graft is needed to fill the defect in opening wedge techniques.
    - Autograft typically is taken from the iliac crest (ie, tricortical iliac crest graft)
    - Allograft combines tricortical iliac crest with croutons for medullary packing. Concerns in regard to placing “dead bone” into the osteotomy site have led to recommendations to include osteoconductive or osteoinductive additives (eg, OP-1, DBM) as well.
- Intraoperative C-arm fluoroscopy should be available.
- Examinations under anesthesia should include assessment of ROM and of varus/valgus stress at 30 degrees and 0 degrees.

Positioning

- The patient is placed supine on the operating table (FIG 3).
- A lateral post is used during the arthroscopy portion of the procedure and can be lowered during the open osteotomy portion.

ARTHROSCOPY

- A routine diagnostic arthroscopy is performed.
- The status of the lateral compartment is confirmed.
  - If unexpected lateral compartment osteoarthritis or chondral defects are found, off-loading the knee into that compartment may be detrimental to the long-term results of the surgery (TECH FIG 1).
- The status of the patellofemoral compartment also is confirmed.
  - Significant patellofemoral arthritis (especially of the lateral patellar facet and lateral trochlea) can be exacerbated with an HTO. Such arthritis also can be detrimental to the long-term results of the surgery.
  - Meniscal tears are débrided back to a stable base.
  - Chondroplasty or marrow stimulation is now performed.
    - If the osteotomy is being performed together with a cartilage restorative procedure (eg, autologous chondrocyte implantation), the osteotomy is performed first and then the restorative cartilage procedures are performed, to minimize any trauma to the newly implanted periosteal covering or injected cartilage cells.

Approach

- The main approach for the opening wedge HTO is through an anteromedial incision, just distal to the medial joint line and 3 cm medial to the tibial tubercle.
- Approaches for the lateral closing wedge are from the anterolateral aspect of the tibia, just anterior to the fibula.
INITIAL DISSECTION

- Proper bony anatomic landmarks are located.
  - The tibial tubercle, posteromedial tibia, and joint line are clearly identified with a skin marker.
  - The incision lies 2 to 3 cm posterior to the tibial tubercle and 1 cm distal to the joint line, and extends distally for 5 to 6 cm (TECH FIG 2A).
  - The incision is taken down through the skin and subcutaneous tissues, revealing the sartorius fascia (TECH FIG 2B).
  - The superior border of the gracilis hamstring tendon is palpated, and the sartorius fascia is opened along the superior border of the gracilis tendon.
  - Medially, the pes bursa is released from the medial tibial tubercle in an inverted L fashion.
  - The pes bursa is carefully elevated distally, taking great care to develop the plane between the bursa and the underlying medial collateral ligament.
  - Proximally, the retinaculum and layer 1 of the knee are incised to the approximate level of the joint line (TECH FIG 2C).

- Anteriorly, the patellar tendon is identified, and a plane posterior to the tendon is identified. A Z-retractor is placed under the tendon to protect it.
  - Occasionally, the most superior fibers of the patellar tendon attachment to the tibial tubercle must be elevated to avoid inadvertent creation of the osteotomy through the patellar tendon.
  - Posteriorly, the MCL is dissected subperiosteally using a Cobb elevator, which is taken back toward the posteromedial border of the tibia.
  - The Cobb elevator is then used to dissect the muscles and tissues from the posterior tibia along the line of the osteotomy. Care must be taken to stay directly on the posterior tibial bone to avoid neurovascular injury.
  - After adequate posterior dissection, it should be possible to pass a finger bluntly across the posterior tibia. For further protection of the posterior neurovascular structures, a laparotomy sponge is placed across the back of the knee.
  - Finally, another Z-retractor is placed posteriorly to retract the pes bursa, MCL, and posterior neurovascular structures (TECH FIG 2D,E).

**TECH FIG 2 • A.** View of the anteromedial knee showing the proper bony landmarks. PMT, posteromedial tibial border; TT, tibial tubercle; arrowhead, joint line; *, level of hamstring tendons. **B-E.** Dissection from an anteromedial view. **B.** Overall orientation of incision through subcutaneous fat, down to sartorius fascia. **C.** Close-up of incision. The sartorius fascia is opened just superior to the gracilis tendon, and the pes bursa is elevated off in an L-type fashion. An incision also is made proximally in the retinaculum. **D.** This incision reveals the fibers of the medial collateral ligament (MCL), which are then dissected subperiosteally with a Cobb elevator. **E.** Retractors are placed under the patellar tendon and at the posteromedial tibia.
PLACING GUIDE PINS

- Commercially available osteotomy systems provide the necessary instrumentation needed to carry out the procedure. We use the Arthrex instrumentation (Arthrex, Inc., Naples, FL).
- Before the osteotomy is performed, an intraoperative mechanical axis view should be obtained, using either the Bovie cord or the alignment rod found in the osteotomy set.

Using fluoroscopy, the alignment rod is placed at the center of the femoral head (TECH FIG 3A) and then at the center of the ankle joint (TECH FIG 3B).

TECH FIG 3 • A. Fluoroscopic image of alignment rod through femoral head. B. Fluoroscopic image of the alignment rod in the center of the ankle. C. The subsequent location of the alignment rod in the knee. This initial mechanical axis must be corrected. It should match with the preoperative planning. D. Initial guide pin from medial to lateral and parallel to the joint line. The pin is placed approximately 1 cm distal to the joint line. E. Osteotomy guide pin assembly over the initial guide pin. The angle of the guide pin assembly is changed so that the guide pins are just superior to the tibial tubercle. Two pins are drilled from medial to lateral along the osteotomy line to intersect the initial guide pin 1 cm from the lateral cortex. F. Fluoroscopic image verifying the two guide pins placed from medial to lateral using the osteotomy guide pin assembly. Note how in this view, which is parallel to the joint surface, the two pins are superimposed on one another, thus verifying that they, too, are parallel to the joint surface. White arrow, guide pin assembly; black arrow, osteotomy guide pins; black arrowhead, initial guide pin.
■ The subsequent location of the alignment rod in the coronal view of the knee is the intraoperative location of the mechanical axis (TECH FIG 3C).
■ These radiographs are saved for later comparison.
■ A guide pin is placed from medial to lateral across the proximal tibia, 1 cm distal to the joint, and parallel to the joint surface.
■ The tip of the guide pin should be just proximal to the level of the fibula. The location of this guide pin should be verified with fluoroscopy (TECH FIG 3D).
■ The osteotomy guide pin assembly is then inserted onto the guide pin (TECH FIG 3E). The guide pin assembly acts on the same concept as an ACL tibial aiming guide, placing the subsequent guide pins at the proper angle and oriented to the tip of the previous guide pin placed parallel to the joint line.
■ A parallel guide sleeve is then inserted onto the osteotomy guide pin assembly.
■ Not only can the osteotomy guide pin assembly determine the angle of the cut in the coronal plane, but it also has the ability to rotate in the sagittal plane to reproduce the anterior-to-posterior tibial plateau slope accurately. This can be helpful in special situations (eg, PCL or ACL deficiency) in which further alterations in the tibial slope may be necessary (eg, a biplane osteotomy).
■ The angle of the guide pin assembly in the coronal plane is set so that the guide pins will enter the proximal tibia above the tibial tubercle.
■ When acceptable, two further guide pins are drilled from medial to lateral along the orientation of the osteotomy cut. Their position is verified with fluoroscopy (TECH FIG 3F).
■ The parallel guide sleeve, guide pin assembly, and initial guidewire parallel to the joint line are now removed.

### CUTTING AND OPENING THE OSTEOTOMY

- An optional cutting guide is available for positioning over the guide pins. Either with or without the cutting guide, an oscillating saw is used to make the osteotomy cut.
- The saw is always positioned on the inferior surface of the guide pins to avoid inadvertent maltracking of the saw toward the joint surface. The oscillating saw is used to cut the tibial osteotomy to within 1 cm of the lateral cortex.
- Fluoroscopy should be used frequently to verify the depth and angle of the osteotomy cut.
- Careful attention should be paid when making the posterior and anterior tibial cortex cuts to avoid injury to the posterior neurovascular structures and patellar tendon, respectively.
- Thin osteotomes are then used to complete the osteotomy cut to within 1 cm of the lateral cortex (TECH FIG 4A).
- To assess whether the osteotomy is ready for distraction, a “valgus bounce test” is performed.
- As when assessing a valgus stress to the knee, a gentle valgus stress is applied to the osteotomy. The osteotomy should easily open 4 to 5 mm and “bounce back” to the closed position.
- This ensures that adequate posterior and anterior cortical cuts have been made.
- An osteotomy wedge is now inserted into the osteotomy cut to gently open the osteotomy to the desired correction.
- If it initially is difficult to open the osteotomy and get the wedge in place, three stacked osteotomes can be placed in the osteotomy cut to gently open the osteotomy and provide the initial plastic deformation of the lateral cortex (TECH FIG 4B).
- Once the wedge can be inserted into the osteotomy cut, it is gently driven across the osteotomy to the desired correction.
- The wedge has laser lines that mark the desired osteotomy opening angle. This angle should be taken from the preoperative templating, and we assume that 1 mm of opening equals 1 degree of correction. Therefore, if your preoperative templating needed an 11-degree correction, the osteotomy guide should be driven to the 11-mm opening laser line. The wedge should be inserted only a few millimeters at a time to allow plastic deformation of the lateral cortex (TECH FIG 4C,D).
- Fluoroscopy should be used to assess the status of the lateral cortex and osteotomy progression (TECH FIG 4E).
- One should be wary of propagation of the osteotomy to the lateral cortex with disruption of the lateral hinge or propagation of the osteotomy intra-articularly. This can be usually felt by a sudden “give” of the osteotomy wedge on insertion.
- The posterior tine of the wedge should be as posterior as possible to avoid an inadvertent increase in tibial slope (TECH FIG 4F).
- The proximal tibia is a triangle in cross-section, so the medial starting point of the posterior tine will be more medial to the anterior tine of the wedge.
- Because of the triangular shape of the proximal tibia, the millimeter reading of the posterior tine will be greater than that of the anterior tine if the osteotomy is in the proper sagittal plane alignment.
- The opening of the anterior half of the osteotomy should be one third the height of the posterior half. This will verify that the tibial slope has not been significantly altered.
Chapter 18  
UPPER TIBIAL OSTEOTOMY

**TECH FIG 4**  
A. Fluoroscopic image showing the thin osteotomes completing the osteotomy cut to within 1 cm of the lateral cortex. *Single black arrow*, osteotomy guide pins; *double black arrows*, osteotome; *, posterior retractor protecting the neurovascular structures.  
B. Stacking the osteotomes in the osteotomy cut to help provide the initial plastic deformation of the lateral cortex.  
C. An osteotomy wedge impacted into the osteotomy cut. The anterior tine reads 10 mm and the posterior tine reads 11 mm, because the proximal tibia is a triangle, as explained in Figure 1A. The laser lines correspond with the desired osteotomy opening angle.  
D. Another view of the osteotomy wedge inserted into the osteotomy site.  
E. Fluoroscopic image showing the osteotomy wedge in place with the guide pins just superior to it. The guide pins are left in place during the opening of the osteotomy to avoid inadvertently propagating the osteotomy. The alignment rod is relied upon to verify the amount of opening of the osteotomy and the change in the mechanical axis. *, osteotomy wedge; *black arrow*, guide pins; *arrowhead*, alignment rod.  
F. The osteotomy wedge handle has been removed, and the posterior tine is seen almost at the level of the posteromedial cortex to avoid the inadvertent increase in tibial slope.

**TECHNIQUES**

- The handle of the osteotomy wedge can be removed *(TECH FIG 5A)*, leaving the anterior and posterior tines in place.  
- The proper-sized osteotomy plate is then inserted into the osteotomy site *(TECH FIG 5B)*. To respect the geometry of the tibial slope, it is recommended that the wedge in the plate be sloped from posterior to anterior.  
- The use of second-generation locking plates is recommended.  
- Before fixation of the plate, the tines are removed from the osteotomy wedge *(TECH FIG 5C)*.  
- The plate is secured with two 6.5-mm fully threaded cancellous screws in the proximal fragment. (It is not necessary to use bicortical screws.) The distal fragment is secured with two 4.5-mm bicortical screws.

**PLATE FIXATION**

- The handle of the osteotomy wedge is removed, and the wedge trial is placed between the tines to confirm the size of the osteotomy plate to be used. *(continued)*
BONE GRAFTING

- Depending on the preference of the surgeon and patient, the osteotomy must be packed with bone graft and the medial cortical margins reinforced with tricortical iliac crest graft.
  - The graft can be auto- or allograft, but this must be determined in discussion with the patient before the operation.

Autograft Iliac Crest and Bone Grafting

- The benefit of autograft iliac crest and bone grafting is that not only are the medial cortical margins of the osteotomy reinforced, but all of the bone graft contains hematopoietic elements and the entire bone formation cascade (TECH FIG 6A).
  - The difficulty with this technique is that it is necessary to prep out the iliac crest, and some morbidity results from taking the iliac crest. Although the morbidity is minimal, there is the possibility of postoperative infection, seroma, and pain.

Allograft Iliac Crest and Autograft Cancellous Bone Graft

- The allograft iliac crest is fashioned into wedges that sit anterior and posterior to the plate.
- The tricortical iliac crest helps to restore the medial cortical margins (TECH FIG 6B).
- The autologous cancellous bone graft can either be obtained from the iliac crest in the standard fashion, or a harvester from the osteochondral autograft transplantation system (OATS; Arthrex, Inc., Naples, FL) can be used to take two plugs of bone from the distal medial femur to pack into the osteotomy site.

Allograft Iliac Crest and Allograft Cancellous Bone Graft

- In this case, we worry about the risk of nonunion with larger osteotomy openings and the amount of bone graft that must be incorporated. Obviously, the larger the correction, the longer it will take for bone graft incorporation.
- If the osteotomy is larger than 11 mm, we routinely use either demineralized bone matrix or OP-1 for added osteoinductive benefits.

CLOSURE

- The pes bursa is reapproximated over the distal portion of the osteotomy plate to its anatomic location with no. 1 Vicryl (TECH FIG 7A).
  - The horizontal incision in the sartorius fascia also is closed with no. 1 Vicryl, as is the proximal split into the medial retinaculum.
  - As much coverage of soft tissue over the plate as possible is attempted. In most cases, with careful initial dissection, the plate can be covered completely.
- A medium Hemovac drain is then placed in the subcutaneous tissue, and the wound is closed in the standard fashion. A sterile dressing is applied and a CryoCuff device (Aircast, Austin, TX) is used (TECH FIG 7B–D).
- The leg is placed into a hinged knee immobilizer, locked in extension.
PEARLS AND PITFALLS

Dissection
- Be sure to dissect the tissues off of the posterior tibia, in line with the proposed osteotomy cut. It should be easy to place the surgeon’s finger across the posterior tibia from medial to lateral. Place a laparotomy sponge along the posterior tibia to further protect the neurovascular structures.

Osteotomy cut
- Pay attention to the sagittal slope of the osteotomy cut to avoid the inadvertent increase in posterior tibial slope. After the osteotomy wedge is in place and the osteotomy is opened, the anterior half of the osteotomy should be one third the height of the posterior osteotomy.
- Before inserting the osteotomy wedge for opening the osteotomy, the cut should have an easy “bounce” to it. If the osteotomy cannot be opened with a slight valgus stress, the anterior or posterior tibial cortex might have been missed with the osteotomes or saw.
- Make the osteotomy cut inferior to the guide pins.
- Use fluoroscopy often to assess whether the osteotomy has propagated intra-articularly or through the lateral cortex. If an intra-articular extension is noticed, it must be addressed like a tibial plateau fracture. If the lateral cortex has been breached, then either a staple or a 2- or 3-hole plate must be placed at the lateral cortex to restore stability to the lateral hinge.

Plate fixation
- Make sure the osteotomy wedge tines have been removed before fixation of the plate so that the osteotomy can compress onto the wedge of the plate and not be fixed in a distracted position.

POSTOPERATIVE CARE
- Immediate postoperative care
  - We admit all of our patients with osteotomies for a one day hospital observation.
  - A patient-controlled morphine drip is used for the first night; the patient is weaned to medication by mouth the next morning.
  - The drain is removed the next morning, before the patient is discharged.
  - Patients are instructed in the immediate use of ankle pumps, straight leg raises, and quadriceps isometric exercises.
- Patients are made non-weight bearing with crutches and the hinged knee immobilizer locked in extension at all times, except for knee ROM exercises.
- Full knee extension is emphasized. Active ROM is allowed to 90 degrees immediately, with or without the brace. No passive ROM is allowed, to avoid any inadvertent stress on the osteotomy site.
- Sequential compression devices are used while in the hospital. Kendall TED anti-embolism knee high stockings (Covidien, Mansfield, MA) and aspirin (650 mg every day) are used for 1 month postoperatively to minimize the risk of deep venous thrombosis.
OUTCOMES

- High tibial osteotomy done with proper indications and meticulous technique can lead to consistent, effective reduction of pain and prolongation of knee arthroplasty for up to 7 to 10 years. Factors associated with poor outcomes include undercorrection of the deformity and obesity.
- Many articles have been written about HTO outcomes (Table 1).

COMPLICATIONS

- Although the HTO can provide many years of pain relief in the physiologically young, arthritic knee, it is not without complications.
  - As with many surgeries, the learning curve is high, and the surgeon should be prepared for the consequences.

Table 1: Results with High Tibial Osteotomy

- Sprenger and Doerzbacher²¹ reported a 21% closing wedge HTO complication rate, and Spahn²⁰ reported a 43.6% opening wedge HTO complication rate.
- Intraoperative complications
  - Fracture of the medial or lateral cortex (FIG 4A)
  - Intra-articular extension of the osteotomy (FIG 4B)
  - Intra-articular screw placement
  - Peroneal nerve palsy
- Immediate postoperative
  - Hematoma
  - Infection
  - Compartment syndrome
  - Thromboembolism
- Delayed postoperative
  - Patella baja
  - Nonunion or delayed union
  - Hardware failure (FIG 4C)
  - Collapse with loss of osteotomy correction (FIG 4D–F)

FIG 4 • A. Lateral cortical breach stabilized with a three-hole 1/3 tubular plate. This was placed after the osteotomy had propagated through the lateral wall of the tibia. B. Intra-articular extension of the osteotomy that was not repaired intraoperatively, with subsequent osteotomy collapse and hardware breakage. C. Hardware failure. There is no collapse of the osteotomy, but the distal screws failed secondary to micromotion. (continued)
REFERENCES

Total knee arthroplasty (TKA) is a successful surgical procedure that provides excellent and durable relief of pain and improvement in functional status for patients with osteoarthritic knees. Cement fixation currently is the preferred method of fixation for TKA.

The knee is a synovial hinge joint with little rotational motion. The stability of the joint is provided by congruity of the joint as well as by the collateral and cruciate ligaments. The mechanical axis is a line drawn from the center of the femoral head, to the center of the tibial articular joint, forming a straight line, and the anatomic axis is the femorotibial axis, created by the intersection of the long axes of the femur and tibia. The intersection of these two axes creates about a 6-degree angle of valgus. The 6-degree valgus angle of the knee is determined by the bony anatomy of the distal femur and the proximal tibia.

The proximal articular surface of the tibia usually is oriented in slight varus—3 degrees, on average. This varus position, combined with the offset of the hip center of rotation, results in the weight-bearing surface of the tibia being parallel to the ground during a single-leg stance. As a result of the slight varus in the tibia, the distal femur actually is in 9 degrees of valgus, resulting in a combined femorotibial alignment of 6 degrees when the knee is in extension.

The asymmetry of the distal femoral condyles is also carried over to their posterior surfaces. When the normal knee is flexed, the joint remains parallel to the floor. For this relationship to be maintained on the varus tibial surface, there must be an asymmetry of the posterior dimensions of the femoral condyles. When observed in flexion, the medial femoral condyle extends more posterior than the lateral femoral condyle.

The sagittal alignment of the tibial articular surface also is important. In the sagittal plane, the tibia is sloped posteriorly about 5 to 7 degrees. In the normal knee, the asymmetry of the bony anatomy maintains the alignment of the joint and ligamentous tension.

Knee osteoarthritis (OA), also known as degenerative joint disease (DJD), is usually the result of wear and tear of the articular cartilage and is seen mostly in elderly women and men. Knee OA can be divided into two types:

- Primary OA: articular degeneration without any apparent underlying reason
- Secondary OA: a consequence of either an abnormal concentration of force across the joint, eg, post-traumatic arthritis (FIG 2), or abnormal articular cartilage, eg, rheumatoid arthritis.

The initial evaluation should focus on identifying the extent to which knee pain is attributable to knee OA. Occasionally pain is referred from the hip joint or lumbar spine to the knee. Although the distinction usually can be made on the basis of physical examination, selective anesthetic injection occasionally is necessary to elucidate the relative contributions of overlapping pathologies to a patient’s symptoms.

With the patient standing, look for periarticular erythema and swelling, quadiceps muscle atrophy, and varus or valgus deformities. Observe the patient’s gait for signs of pain or abnormal hip motion.

If surgery is being considered, systematically assess the surrounding skin for mobility and for the presence and location of scars from any previous surgical procedures (previous scars may influence surgical approach).

Palpate along the joint line, medial and lateral collateral ligaments, iliotibial band, and pes anserine to identify any tenderness suggestive of focal injury.

Active and passive range of motion (ROM) should be assessed. Normal ROM should be from full extension (0 degrees) to full flexion (135 degrees). Any deviation from this normal range should be documented.

The strength of the quadiceps and hamstring muscles should be assessed and documented using a five-point scale.

Palpate and document popliteal, dorsalis pedis, and posterior tibial pulses. Evaluate the patient’s legs for shiny, hairless skin or venous stasis ulcers, which raise concern for vascular problems.

Other methods for examining the osteoarthritic knee before arthroplasty include the following:

- A Q angle of more than 15 degrees often is the cause of patellar subluxation/dislocation or patellofemoral pain and arthritis.
- Anterior drawer test: Increased anterior translation of the tibia compared to the other side plus a mushy endpoint indicates anterior cruciate ligament (ACL) deficiency.
Posterior drawer test: Translation of the tibia more than 10 mm posterior to the femoral condyle is highly suggestive of multiligamentous knee injury and deficiency of the posterior cruciate ligament (PCL).

Varus and valgus stress test: Instability at 30 degrees of flexion suggests isolated collateral ligament injury. Instability at both 0 and 30 degrees is suggestive of a multiligamentous injury.

Patellar apprehension test: A patient with a history of patellar instability may report a sensation that his or her patella feels as if it is about to dislocate.

Patellar tilt test: More than 15 degrees of lateral tilt is suggestive of laxity. Lack of patellar tilt is suggestive of a tight lateral constraint.

The patellar grind test reveals pain or crepitus.

Quadriceps active test: Forward translation of the tibia after attempted knee extension is positive for PCL insufficiency (reduction of posterior tibial sag).

IMAGING AND OTHER DIAGNOSTIC STUDIES

The standing anteroposterior (AP) radiograph best reveals joint space narrowing and any potential dynamic instability. It also shows any marginal osteophytes, tibial and patellar spurs, subchondral sclerosis, joint space narrowing, flattening, squaring of the condyles, and joint line angulation.

Standing lateral in extension

Skyline view of the patella

Occasionally, specialized views of the knee such as the 45-degree posteroanterior (PA) view of the knee (Rosenberg view) or a long-leg view may be required to determine the degree of deformity, and also to obtain information about the status of the femur and tibia in patients with a history of previous trauma or fracture.

DIFFERENTIAL DIAGNOSIS

Any potential cause of local or diffuse knee pain should be considered in the differential diagnosis of knee osteoarthritis, including:

- Hip arthritis
- Low back pain / spinal stenosis
- Patellofemoral syndrome
- Meniscal tear
- Bursitis
- Infectious arthritis
- Gout, pseudogout
- Iliotibial band syndrome
- Collateral or cruciate ligament injury
NONOPERATIVE MANAGEMENT

- A wide range of nonoperative modalities are available for treatment of knee OA. These interventions do not alter the underlying disease process, but they may substantially diminish pain and disability.
- Health and behavior modifications, including patient education, physical therapy, weight loss, and knee braces, can result in improvement of knee pain and function. In all stages of knee OA, weight loss (if the patient is overweight) is valuable. An unloader-type knee brace shifts load away from the involved knee compartment, whereas a support-type brace supports the entire knee load.
- Drug therapy includes acetaminophen, nonsteroidal anti-inflammatory drugs (NSAIDs), COX-2 inhibitors, and glucosamine and/or chondroitin sulfate.
- Intra-articular injections
  - Corticosteroid injections in knees with considerable inflammatory component (eg, swelling) are useful.
  - Hyaluronic acid (viscosupplementation)

SURGICAL MANAGEMENT

- Osteotomy may be indicated for unicompartmental knee OA associated with malalignment, or for correction of symptomatic posttraumatic malunions about the knee.
- Arthroscopic débridement and lavage has a minimal role in the treatment of knee OA.
- Arthroplasty: total or partial knee replacement

Indications

- TKA is regarded as a valuable intervention for patients who have severe daily pain along with radiographic evidence of arthritis. The discrepancy between the severity of radiographic changes and symptoms poses a problem. A painful knee without associated radiographic findings dictates a systematic search to exclude other possible sources of knee and leg pain (ie, referral pains from hip or nerve root compression in the spine). The need for correction of significant or progressive deformities sometimes may be considered an indication for knee replacement in patients with moderate arthritis.

Contraindications

- Absolute
  - Active or latent (<1 year) knee sepsis
  - Presence of active infection elsewhere in the body
  - Incompetent quadriceps muscle or extensor mechanism
- Relative
  - Neuropathic arthropathy (eg, Charcot arthropathy)
  - Poor soft tissue coverage or skin conditions such as uncontrolled psoriatic lesions in the vicinity of the incision
  - Well-functioning and painless knee ankylosed in a good position
  - Morbid obesity
  - Noncompliance due to major psychiatric disorders, including dementia, hostile personality, or alcohol or drug abuse
  - Insufficient bone stock for reconstruction
  - Poor health or presence of comorbidities that make the patient an unsuitable candidate for major surgery and anesthesia
  - Patient’s poor motivation or unrealistic expectations
  - Severe peripheral vascular disease

Preoperative Planning

- A comprehensive medical and drug history is mandatory to confirm that the patient is an appropriate candidate for a major surgery and anesthesia, because an overlooked detail may lead to a serious or life-threatening complication.
- Good-quality radiographs must be obtained, as described earlier. Radiographs are position-sensitive, and care must be taken to obtain the films in neutral rotation. A full-length radiograph from the hip to the ankle is helpful in determining the mechanical axis of the limb and noting unusual shaft bowing or deformities in some cases.
- Template overlay is used to estimate component size and bone defects.
- The patient is required to complete an informed consent regarding the possible risks.

Positioning

- The skin around the knee is shaved using clippers shortly before the procedure in a holding area outside the room where the procedure will be performed. Shaving should be performed in such a manner that skin integrity is preserved.
- The patient is positioned supine on the operating table in an operating room equipped with laminar airflow. The upper torso is secured with a protective belt to allow tilting of the table as needed. A bump is taped to the table in such a position that it supports the heel when the patient’s knee is flexed and frees the assistant’s hands (FIG 3A).
  - A tourniquet is applied snugly and as far proximally as feasible to the upper thigh on soft Webril (Medco, Tonawanda, NY) padding. In obese or short-limbed patients, it may be necessary to use a sterile tourniquet to ensure adequate access to the surgical field.
  - The heel is suspended in a leg holder (FIG 3B).
  - An adhesive drape is put in place distal to the tourniquet to prevent antimicrobial solutions from dripping under the tourniquet.
  - Surgical skin preparation is begun using a broad-spectrum germicidal agent, eg, combined povidone-iodine and isopropyl alcohol solution. Chlorhexidine may be used if the patient is hypersensitive to iodine.
  - Meticulous and secure draping technique is important to reduce the risk of infection. Bulky drapes obscure the palpable bony landmarks, such as malleoli or metatarsal bones, that are routinely used for accurate bone cuts, rotation, and alignment in knee arthroplasty.
  - The limb is exsanguinated by applying an elastic wrap. The incision is marked on the front of the knee along with several horizontal lines that will be used to align the skin properly during closure (FIG 3C). An adhesive plastic surgical drape is placed around the leg without covering the incisional site.
  - A single dose of cefazolin or cefuroxime is administered 30 to 60 minutes before the skin incision is made and 10 minutes before the tourniquet is inflated. If the patient has a β-lactam allergy, alternatives such as vancomycin or clindamycin can be used.

Approach

- Classically, an anterior longitudinal midline incision is used for TKA. This incision may sacrifice the infrapatellar branch of the saphenous nerve, causing an area of lateral numbness; the patient should be warned about this possibility before the surgery.
  - Blood is primarily supplied to the skin of the anterior aspect of the knee from the medial side, so before the skin incision is made, the exact site and size of any previous scars should be taken into consideration; otherwise the viability of
the lateral flap is endangered. In most cases, the preexisting anterior longitudinal scar on the knee is incorporated into the incision, provided that it gives adequate exposure without placing any undue tension on the skin during the operation.

- When parallel anterior longitudinal scars are present, the most lateral one should be used if possible. If this is not possible, a wide bridge of intact skin (8 cm) should be allowed between the new incision and the previous scar. The horizontal scars can be crossed at right angles, and the short oblique ones may be ignored. Acute angles of intersection must be avoided.

- Arthrotomy can be performed by the medial parapatellar approach, the subvastus (Southern) approach, or the midvastus approach.

- The medial patellar approach provides excellent exposure and is associated with a very low incidence of tibial or femoral complications.

**EXPOSURE**

- With the knee in 90 degrees of flexion, the incision (TECH FIG 1) is made from the superior edge of the quadriceps tendon proximally (one hand-breadth above the superior pole of the patella) to the inferomedial aspect of the tibial tuberosity. Flexion tenses the skin and retracts the skin margins as the incision is made.

- The skin, fat, and fascia are incised directly down to the extensor mechanism, and the medial and lateral flaps are reflected only as far as necessary to have adequate exposure while preserving their blood supply.

- Once the deep fascia is opened, the prepatellar bursa is incised and retracted medially and laterally. The paratenon of the patellar tendon should be exposed and protected.

**ARTHROTOMY**

- Bring the knee into extension and perform the arthrotomy.

- Several approaches are described in the following sections, these differ mainly in the proximal part of the incision (TECH FIG 2).

**Medial Parapatellar Approach**

- The quadriceps tendon is cut longitudinally from proximal to distal along its medial border, leaving a cuff of tendon approximately 5 to 10 mm wide. Then the incision is carried further, skirting along the medial border of the patella and patellar tendon.

- The arthrotomy incision is made through the medial retinaculum, capsule, and synovium, leaving a 5-mm cuff of retinaculum attached to the patella to facilitate repair at the end of the procedure. Distally, the incision should stop at the inferior aspect of the patellar tendon insertion, proximal to the inser-
**KNEE RECONSTRUCTION**

**TECH FIG 2** • Planes of dissection for the medial parapatellar approach, the midvastus approach, and the subvastus approach.

**KNEE JOINT EXPOSURE**

- The soft tissue sleeve is dissected from the proximal medial tibial metaphysis (TECH FIG 3) by taking the amount of varus or valgus deformity into account.
  - More extensive dissection is performed for knees with varus deformity, and limited or no dissection for knees with valgus deformity.
  - With sharp dissection or cautery, a subperiosteal layer that includes the deep medial collateral ligament (MCL) is raised carefully from the medial tibial flare to the sagittal midline of the tibia. The dissection must not be extended more than 2 to 3 cm distal to the medial joint line.

**Subvastus (Southern) Approach**

- Blunt dissection is carried from the medial intermuscular septum. Care should be taken to avoid damaging the intermuscular septal branch or the articular branch of the descending genicular artery. This should be avoided by limiting proximal dissection to 10 cm or less.
  - A transverse incision is made at the mid-patella through the medial retinaculum and inferior to the vastus medialis.
  - This incision is stopped once the patellar tendon is reached, and a second incision is made along the medial border of the patellar tendon approximately 1 cm along the medial border to the tibial tubercle.

**Midvastus Approach**

- Blunt finger dissection is begun at the superomedial pole of the patella in the midsubstance and through the full thickness of the vastus medialis muscle, and is extended parallel to its fiber, to a maximum of 4 cm proximomedial to this starting point. By doing this, the incision does not extend far enough medially to violate the saphenous nerve to the vastus medialis obliquus. The medial superior geniculate artery and the muscular branches of the descending geniculate artery are similarly preserved.

**Patellar Eversion**

- The patella is everted, and the knee is flexed (TECH FIG 4A). The medial flap of the quadriceps must be reflected medially off the face of the femur. There should be no undue tension at the patellar tendon insertion. Placing one smooth pin in the tibial tuberosity may provide some protection against tendon avulsion.
  - A 90-degree angled Hohmann retractor is inserted laterally to the lateral meniscus (TECH FIG 4B).
  - The synovial layer surrounding the patella is excised to expose the insertion of the quadriceps and patella tendons. Osteophytes are trimmed with a rongeur to establish the true size and thickness of the patella.
  - To permit full eversion of the patella, the capsular folds of the suprapatellar pouch proximal to the patella are released.
  - If the patella will not evert, the dissection across the lateral tibial plateau is revisited, and the incision in the proximal quadriceps is examined to see whether it has been opened proximally enough. Division of the lateral patellofemoral ligament makes it easier to evert the patella.
  - Release of a portion of the medial portion of the patellar tendon and elevation of a small cuff of periosteum immediately adjacent to the patellar tendon insertion can be helpful.
■ With the tibia completely subluxed anteriorly, the medial and lateral menisci are excised and the PCL exposed, released, or excised, as the surgeon prefers. The popliteus tendon is protected during all soft tissue and bone resection.

■ If adequate exposure cannot be obtained, the femoral cuts should be made first, allowing access to the back of the joint.

■ An anterior synovectomy is performed to expose the supracondylar region of the femur. This is essential to allow for proper and precise sizing of the femoral implant and to prevent notching.

**PREPARATION OF THE TIBIA**

■ The ACL is excised, allowing further anterior translation of the tibia.

■ When combined with external rotation as the knee is flexed, complete anterior subluxation of the tibia from beneath the femur can be accomplished, providing complete exposure of the tibial plateau, femoral condyles, and posterior horn attachments of the menisci.

■ Rarely, this maneuver may be blocked by osteophytes, which should be removed. If the posteromedial corner and posterior capsular structures are not released adequately, anterior translation and external rotation cannot be accomplished.

■ A retractor is applied to gently retract the tibia forward so that exposure of the posterior tibial plateau is achieved.

**BONE CUTS**

■ The five standard bone cuts for any TKA are as follows:
  ■ Transverse upper tibial cut
  ■ Distal femoral condyles resection
  ■ Anterior and posterior condylar resections
  ■ Anterior and posterior chamfer cuts from the distal femur
  ■ Retropatellar cut

■ The sixth step of the intercondylar box cut is performed only for posterior stabilized designs.

■ The surgeon performs either the femoral or the tibial cut first. Generally, when the tibia can be easily shifted anteriorly, the tibia is cut first, but if the knee is tight or good exposure is difficult to obtain on the tibial plateau, the femoral condyles are the first to be cut.

■ Bone cuts can be made using open or slotted cutting guides (**TECH FIG 5**). The cutting slots are more accurate and reduce human error. In practice, however, they obscure the saw blade tip, potentially increasing the risk of injury to important structures such as the MCL. Most newer femoral cutting blocks provide slots for performing distal, anterior, posterior, and chamfer cuts by using a single block, thereby reducing the time.

■ Clinical success of TKA is correlated with correct orientation of the components and the resultant lower extremity alignment. Accuracy of component posi-
tioning relies on alignment guides for making precise and accurate bone cuts.

**Upper Tibial Cut**

- An intramedullary (IM) rod can be used provided that there is no deformity, bowing, offset to the tibial shaft, or blockage in the medulla. By and large, the extramedullary (EM) alignment guide is preferable, because it can bypass any potential deformity of the tibial shaft.
  - In obese patients those bony landmarks are masked, however, and an EM guide may cause more error.
- Tibial cut using an extramedullary guide
  - Attach the strap of the distal end of the alignment guide above the ankle, and pin the proximal end to the upper tibial metaphysis (TECH FIG 6A). Necessary adjustments must be made to make the guide align with the center of the interspinous eminence of the plateau, the tibial shaft, and the middle of the ankle mortis, which is, in fact, 3 to 5 mm medial to the intermalleolar axis.
  - By sliding the distal end of the guide mediolaterally at the ankle, a final adjustment can be made to centralize it over the center of the talus and to minimize the risk of varus inclination of the cut.
  - Set the proximal part to obtain 3 to 5 degrees of posterior slope in the sagittal plane.
- Bear in mind that jig systems fitted to the anterior surface of the proximal tibia will have a tendency to align in excessive internal rotation due to the everted patellar tendon. To avoid this error, center the jig on the medial third of the tibial tuberosity.
- Fit the proximal cutting block snugly up against the tibial cortex to improve the accuracy of the resection.
  - This cut should be made at right angles to the anatomic axis of the tibia in the coronal plane.
- Remove 10 mm of cartilage and bone from the least involved plateau. The bone resected should have approximately the same thickness as the final tibial component, including the metal base plate and polyethylene liner.
- Make the tibial cut using an intramedullary guide.
  - If you opt to use an IM guide, accurately choose the pilot hole that is at the junction of the tibial insertion of the ACL and the anterior horn of the lateral meniscus (TECH FIG 6B). By irrigation and aspiration of the canal, insertion of a fluted, hollow rod, and drilling a hole slightly larger than the size of the IM rod, the risk of fat embolization can be reduced.
  - Insert the IM rod and fix the cutting block in the desired position, then remove the rod together with its outrigger.
  - Use an oscillating saw to cut the bone. To protect the posterior neurovascular bundle, stop cutting the last few millimeters of bone by saw and crack the rest afterward by levering or using an osteotome.
  - Carefully protect the MCL and LCL by proper insertion of retractors.
  - Remove the osteotomized bone along with the remnants of menisci. Establish the anatomic boundary of the tibial metaphysis by removing the osteophytes.

**Distal Femur Cuts**

- Because of a lack of reliable palpable external landmarks, the IM alignment guide is superior to the EM guide for preparation of the femur, except in cases of excessive femoral bowing, previous fracture, Paget disease, or an ipsilateral long-stemmed total hip replacement.
- Drill an entry hole 1 cm anterior to the origin of the PCL, slightly medial to the midportion of the intercondylar
notch (TECH FIG 7A). Touching the anterior surface of the femoral shaft with the other hand can be a good guide to the direction of drilling.

- Simple measures such as slight overdrilling, using a fluted IM guide, and aspiration of the marrow contents before insertion of the guide are recommended to decompress the femoral canal and to subsequently reduce the risk of fat emboli.
- Insert the IM guide and pass it directly in the center of the canal without making any contact with the femoral cortices—otherwise, the angle of resection will be changed. Attach the cutting block to the IM rod, adjust it at 5 to 6 degrees of valgus, and then fix it in place.
- Cut valgus knees in no more than 5 degrees of femoral valgus. Check to be sure that there is no soft tissue in the area below the guide.
- Remove the IM rod and cut the bone. It is crucial to prevent the saw blade from bending or going forward in an undesired direction while proceeding through the osteotomy line, particularly during resection of hard and sclerotic bone.
- The amount of bone to be resected should be precisely equivalent to the thickness of the final femoral component. In the sagittal plane, the distal femur should be cut at 90 degrees to the femoral mechanical axis and, after soft tissue balancing, should be parallel to the resected surface of the proximal tibia (TECH FIG 7B,C).

Anterior and Posterior Femoral Condyle Cuts

- Making accurate cuts is essential to obtain proper size and rotation of the final femoral component.
- Use the AP sizing guide to aid in setting 3 degrees of external rotation of the femoral component in relation to the posterior condylar axis. External rotation means counterclockwise rotation for the right knee and clockwise rotation for the left knee. In knees without deformity, external rotation usually results in removal of more bone from the medial posterior condyle. Erosion of the posterior femoral condyles can distort this posterior condylar axis.
- Appreciating that the posterior cut should be parallel to the transepicondylar line, perpendicular to the Whiteside line (AP axis of the femoral sulcus), and parallel to the upper tibial cut can help the surgeon reduce any error in the rotation of the femoral component (TECH FIG 8A).
- Maximally flex the knee to reduce the chance of injury to the posterior neurovascular bundle during posterior sawing. Adjust the stylus that indicates where the anterior cut exits the femur. Pass the anterior cut tangential to the anterior femoral cortex to avoid notchting and subsequent stress rising for a fracture (TECH FIG 8B–D).
- Conversely, a cut that is too high causes an oversized femoral component and overstuffing of the patellofemoral articulation, which can subsequently cause patellar maltracking or limit range of flexion.

Anterior and Posterior Chamfer Cuts

- Anterior and posterior chamfer cuts are essential for the prosthesis to fit over the distal femur.
- A chamfer guide is placed on the distal femur. In some systems this step is integrated into the same block as that used for the anterior and posterior femoral cuts (TECH FIG 9A,B).
- When the sawing is complete, use a lamina spreader to open the space between the femur and the tibia, and then use an osteotome to free small remnant portions of uncut bone (TECH FIG 9C).

Patellar Preparation

- Remove the osteophytes, synovial insertions, and fat to demarcate the anatomic margins of the patella.
- Use a caliper (TECH FIG 10A) to assess the patellar thickness before the cut and after the patella is resurfaced to ensure that the patellar thickness is equal to the original thickness and that at least 12 mm of bone stock remains.
- To obtain an exact measurement of the patellar thickness, the prepatellar bursa should be dissected to completely expose the anterior surface of the patella.
- Use a patellar cutting jig or a freehand technique. Pass the patellar cut parallel to the anterior surface of the patella through the chondro-osseous junction, completely resecting both facets (TECH FIG 10B).
the cut passes just superficial to the quadriceps insertion; distally, it passes through the nose of the patella.

- Make a flat cut removing any remnants of cartilage.
- Center and firmly hold the appropriate drill guide and drill three lug holes in a triangular arrangement (TECH FIG 10C,D).

To accommodate the post-cam mechanism in the posterior stabilized prosthesis, place the finishing guide onto the distal femur to make the intercondylar box cut (TECH FIG 10E). Center the guide mediolaterally and secure it firmly by pin or screw.

- Use a reciprocating saw to resect the bone from the notch. Complete the resection with a chisel or osteotome.
Chapter 19  CEMENTED TOTAL KNEE ARTHROPLASTY

TECHNIQUES

Soft tissue and ligament balancing is a vital portion of the surgical procedure. In knees with minimal deformity, balancing is not challenging, and it often can be achieved by performing a minimal soft tissue release, making the bone cuts, and then checking the knee by insertion of trial components. In knees with complex or severe deformity, however, cautious stepwise release is necessary. Insert the trial components and check the balance of the knee after each step of the procedure. If no release is necessary, proceed to the next step. When the deformity is severe and leads to loss of the integrity of the ligaments, be ready for application of a constrained prosthesis.

To achieve a proper soft tissue balance, initially remove the offending osteophytes until the anatomic margins of the bone are determined.

Correction of Flexion Contracture
- Use a curved osteotome to release osteophytes in the back of the femur and then extract them with a rongeur.
- Strip the adherent capsule from the posterior aspect of the femur to reestablish the original recess.
- In knees with preoperative moderate to severe flexion contracture, it also is necessary to cut the posterior capsule transversely and to release the tendinous origins of the gastrocnemius.
- Perform recession or resection of the PCL if it is still preserved.
- Resect additional bone from the distal femur.

Correction of Varus Deformity
- The medial capsulotomy, along with subperiosteal medial release, which is included in the initial approach and exposure, can correct minimal varus deformities.
- Extend the medial subperiosteal release for an additional 2 to 3 cm.
- If the medial knee is tight in flexion only, release the anterior portion of the superficial MCL.
- If the medial knee is tight in extension only, release the posterior oblique fibers of the superficial MCL.
- If the medial knee is tight in both flexion and extension, release elements of the superficial MCL.

Correction of Valgus Deformity
- If the lateral knee is tight in extension, release the iliobial band. Some surgeons prefer the “pie-crusting” technique.
- If the lateral knee is tight in flexion, release first the popliteal tendon and then the LCL subperiostealetly from the femoral condyle.
- If the lateral knee is tight in both flexion and extension, sequentially release the iliobial band, the poplitea tendon, the LCL, and finally the posterior capsule.
- Release the biceps femoris tendon only when absolutely necessary.

Correction of Valgus Knee With Incompetent Medial Collateral Ligament
- A valgus knee with an incompetent medial collateral ligament occurs in knees with severe, longstanding valgus deformity.
- Treatment strategies include the use of a varus–valgus constrained articulation, MCL advancement, or MCL reconstruction.
COMPONENT INSERTION AND TRIAL REDUCTION

- Insert provisional femoral and patellar components of the correct size (TECH FIG 11A).
- Next, insert a tibial sizing tray that matches the surface area of the tibial cut. This sizing tray is a jig for drilling final fixation holes for the tibial component and determines its ultimate mediolateral, anteroposterior, and rotational position.
  - Some rotational change is still possible at this point. Internal rotation of the component must be avoided.
  - Check all around the tray to ensure that there is no overhang, especially on the medial side, where overhang may be easily overlooked.
- Insert a spacer of the proper height and reduce the joint. Check the ROM and ligament stability. Apply varus and valgus stresses in both flexion and extension to determine the stability of the knee and the appropriate thickness of the tibial insert.
- At this stage it is particularly important to do meticulous ligament balancing for PCL-retaining designs by using different thicknesses of tibial trial components.
- Align the center of the tibial tray over the medial third of the tibial tubercle and pin it in place (TECH FIG 11B).
- Assemble the proper size of tibial broach on the broach impactor. Seat the impactor on the tray and impact the broach to the proper depth (TECH FIG 11D).
- Check the patellar tracking during ROM.
- Once trial reduction is complete, extract all components.

COMPONENT FIXATION

- Polymethylmethacrylate is used for fixation of the components in knee arthroplasty. The setup of all components and basic instruments for component insertion should be done before the cement is prepared (TECH FIG 12A,B).
- Drill the tibial plateau in the sclerotic parts (1 to 2 mm deep) to achieve adequate anchorage of the tibial component.
- Plug the IM hole of the distal femur with small pieces of cancellous bone (TECH FIG 12C).
- Use pulsatile lavage to thoroughly irrigate the cut surfaces with normal saline in order to remove all debris and increase the depth of cement penetration into the trabecular bone. When done, be sure to dry the bone completely.
- Put some gauze sponges on the cut surfaces and use a hand to press down on the sponges to keep the bones dry until the cement has been prepared by vacuum mixing.
- When the cement is in a doughy state, apply it to the tibial plateau (TECH FIG 12D). Add a thin layer of cement,
then impact the tibial component and polyethylene liner into place (TECH FIG 12E).
- Trim and remove the excess cement as it extrudes from under the plateau.
- Apply cement to the femoral cut surfaces (TECH FIG 12F), especially the posterior condyles, which tend to be undercemented.
- Impact the femoral component into position, and remove the excess cement from around the prosthesis (TECH FIG 12G).
- In areas that are clearly visible, trim the cement by scalpel and then remove it by curette; in areas that are not easily seen, do not use a scalpel to trim the cement.
- Reduce the knee and bring it to full extension.
- With the knee extended, apply cement to the patella (TECH FIG 12H). Insert the patellar component and clamp it firmly in place (TECH FIG 12I). Trim and remove the excess cement.
- Keep the knee in full extension until the cement is fully cured. Inspect all the corners of the joint, especially the posterior parts, to make certain that no extra cement remains, because extra pieces could block knee ROM or act as loose bodies in the knee, producing third-body wear.
- Irrigate the knee thoroughly. For the last time before closing the joint, check the ROM, knee stability, and patella tracking.

**TECH FIG 12** • All components (A) and basic instruments for component insertion (B) are set up in advance of cement preparation. C. The intramedullary hole of the distal femur is plugged with small fragments of cancellous bone. D. Cement is applied to the tibial plateau. E. A thin layer of cement is added to the tibial tray, and the tibial component and polyethylene liner are impacted into place. F. Cement is applied to the femoral cut surfaces and the femoral component. G. The femoral component is impacted into position. H. Cement is applied to the patella. I. The patellar component is inserted and clamped firmly.
**PEARLS AND PITFALLS**

**Distal position of extramedullary tibial guide**
- If not shifted 3 to 5 mm medially from the intermalleolar axis, varus orientation of the tibial guide will result.

**Orientation of the tibial guide when cutting the tibia to be sloped posteriorly**
- If the cutting guide is internally or externally rotated, the posterior slope will translate into valgus or varus inclination, respectively.

**Coronal position of tibial component**
- A medially located tibial component increases both the Q angle and medial overhang.

**Starting point for femoral IM rod insertion**
- A starting point that is too lateral or too medial will increase valgus and varus angulation, respectively.

**Size of femoral component**
- Undersizing introduces the risk of anterior notching or overresextion of the posterior femoral condyle.
- Oversizing can cause overstuffing of the flexion gap or patellofemoral joint, depending on the position in the sagittal plane.

**Position of femoral component in sagittal plane**
- In neutral alignment, neither flexed nor extended.

**Distal femoral cut**
- This cut should never exceed 7 degrees. Otherwise the Q angle will increase, leading to patellar subluxation or dislocation.

**Using only the posterior condylar line as the reference**
- In the presence of lateral or medial condyle erosion or hypoplasia, this results in excessive internal or external rotation of the femoral component, respectively.

**Medial–lateral femoral component positioning**
- Center the femoral component on the end of the femur or slightly laterally, to aid with patellofemoral kinematics.
- Avoid medial or lateral overhang, because this can result in soft tissue irritation.

**Coronal position of the femoral component**
- Medialization of the femoral component must be avoided, because this increases the Q angle.

**Size of femoral component**
- When it is between two sizes, select the smaller size because mild notching (not more than 1–2 mm) is more palatable than overstuffing the patellofemoral joint.

---

**PATELLA TRACKING**

- With the trial components in place and after the insertion of the final components, evaluate patella tracking throughout a full ROM. The patella should track centrally in the trochlear groove without lateral subluxation or lateral tilt in full flexion.
- Perform the no-thumbs test by reducing the patella and taking the knee through the full flexion arc without closing the medial arthrotomy and without applying any medial force with the thumb to keep the patella in position.
- Extensor mechanism balance has been achieved if the patella does not tilt, subluxate, or dislocate during flexion.4

- If there is patellar tilting or slight subluxation with the no-thumbs test, reapproximate the medial retinaculum at the superior pole of the patella with a single no. 0 suture. If the suture does not break through full flexion of the knee, a lateral release is not necessary. Doing this eliminates slight tilting or subluxation that occurs with the no-thumbs test and avoids an unnecessary lateral release.
- To improve the accuracy of these evaluations of extensor mechanism balance, these tests can be performed with the tourniquet deflated, because an inflated tourniquet can alter patellar tracking by binding the extensor mechanism, resulting in perceived patellofemoral maltracking.4

---

**CLOSURE**

- Copiously irrigate the knee to ensure that no bone or cement particles remain.
- Identify the formerly placed markings. Close the arthrotomy (quadriceps and medial retinaculum) in extension by interrupted suture, in order to produce a watertight seal.
- Place the knee through a full ROM to make sure that the closure is strong enough not to disrupt during physical therapy, and to confirm that the patella is tracking normally.

- Try to cover the prosthesis fully. Close subcutaneous tissue and superficial fascia with interrupted No. 2 Vicryl stitches or its equivalent in a single layer. (Use a double layer if the patient is obese.)
- Close the skin with staples. Sutures that are either too taut or too loose can lead to wound healing problems or wound dehiscence.
POSTOPERATIVE CARE

- At the conclusion of the operation, apply a compression bandage from toes to mid-thigh with 50% overlap of each turn to achieve a uniform double layer, then release the tourniquet. Compression dressings are removed after 24 hours.
- Adequate analgesia via application of improved pain management modalities (eg, intravenous patient-controlled analgesia or patient-controlled epidural analgesia), should be a priority during rehabilitation to hasten early convalescence.
- Administer antibiotics for 24 hours. Start the proper thromboprophylaxis.
- The staples usually are removed after 2 weeks in the first postoperative follow-up visit.
- The aim of rehabilitation is to restore the highest possible range of mobility in and full muscular control of the operated knee. Adequate rehabilitation is an important requirement for successful TKA; in fact, this starts preoperatively (1 to 2 weeks before surgery) by education on the surgical process and outcomes, instruction on a postoperative exercise program, and assessment of the patient’s home and social circumstances. At the hospital and at home, physical therapists play an important role in the rehabilitation process.
- The specific rehabilitation program after TKA is somewhat controversial. As a general rule, patients are encouraged to work on the ROM of the prosthetic knee and to progressively increase their activities as tolerated, but excess activity and stresses should be avoided. Overzealous physical therapy (PT) in the immediate postoperative period may lead to swollen stiff knees and damage.
- Although the continuous passive motion (CPM) machine supposedly does not alter the ultimate amount of knee flexion and overall functional outcome, and CPM protocols vary considerably among institutions, a high degree of flexion in the immediate postoperative period produces quicker restoration of ROM, and CPM in conjunction with physical therapy may offer beneficial results compared to physical therapy alone in short-term rehabilitation. The patient should be informed that final ROM after surgery is directly related to preoperative ROM—in other words, if the preoperative ROM is limited the patient is less likely to achieve knee flexion more than 100 degrees postoperatively.
- On the first postoperative day, bed mobility and transfer training (ie, from bed to chair and from chair to bed) and bedside exercises (eg, ankle pumps, quadriceps sets, and gluteal sets) begin.
  - With a cemented knee, full weight bearing under the supervision of a therapist is allowed on the first or second postoperative day.
  - Ambulation initially is done with a walker until the patient has achieved adequate balance to use canes.
  - A knee immobilizer sometimes may be worn by the patient until he or she can do straight leg raising without difficulty.
- Ambulating with weak quadriceps muscles can lead to instability or giving way of the knee, which can be painful and may lead to unnecessary stress on the prosthesis.
- On the second postoperative day, active ROM, active-assisted ROM, terminal knee extension, straight leg raises, and muscle strengthening exercises start. Gait training with an assistive device, moving from a sitting to standing position and vice versa, and toilet transfers continues.
- On the third to fifth postoperative days, progression of ROM, strengthening exercises to the patient’s tolerance, and ambulation on level surfaces and stairs (if applicable) with the least restrictive device possible are done.
- During the hospital stay, the physical therapist teaches the patient stair climbing with a walker or crutch.
- Patients usually are discharged 3 to 5 days after surgery, to home, inpatient rehabilitation, or a skilled nursing facility, based on individual need in consultation with social work and home health services. Discharge directly to home is preferred.
- From day 5 to 6 weeks, the patient increases ambulation distance and independence in activities of daily living as tolerated.
- Patients can start driving when they are able to operate the pedals safely and rapidly, which usually takes 4 to 6 weeks. Return to work usually takes 4 to 10 weeks, depending on work obligations. Laborers should bear in mind that they may not be able to return to their previous activity level.
- Patients are followed up routinely at 6 weeks, 3 months, and 1 year after surgery. Once strength, mobility, and balance are regained, patients can resume low-impact sport activities (eg, cycling, swimming, gentle aerobic-style exercises, walking, hiking, golf, bowling). High-impact activities such as football, soccer, hockey, and baseball are discouraged.

OUTCOMES

- TKA is a reliable and predictable surgery, with reported survival rates above 85% with 10 to 23 years of follow-up. Favorable gains for pain and functionality following TKA are well reported and recognized.
- For most patients, overall satisfaction with the outcome of the surgery is good to excellent.

COMPLICATIONS

- The overall mortality rate following TKA is very low, and this procedure does not considerably reduce the life expectancy in patients with OA.

Infection

- Because pain is a strong associated symptom, infection should be considered in any persistently painful TKA or with the acute onset of pain in a previously well-functioning TKA.8

- Underresection can result in overstuffing of the patellofemoral joint, leading to excessive lateral soft tissue tension, patella maltracking, anterior knee pain, and limited flexion.
- Overresection may result in patellar fracture or osteonecrosis. Decreasing the overall thickness of the patella can result in extensor mechanism weakness.

Radiographs must be carefully studied for signs of probable infection. Progressive prosthetic loosening is the most consistent radiographic sign. In the presence of infection, erythrocyte sedimentation rates and C-reactive protein levels are elevated. The white blood cell count is not a reliable indicator of infection. Aspirate from the knee joint should be evaluated by synovial fluid analysis, Gram stain, culture, and antibiotics sensitivity. Cultures of superficial wounds or sinus tracts are unreliable and misleading. The preferred specimens are joint aspirate, deep wound biopsy, or bone biopsy.  

Superficial incisional infection, characterized by erythema, dry wound, nonpurulence, and neither loculation nor induration, may be treated with systemic antibiotics with the understanding that once antibiotic therapy is initiated, the opportunity to diagnose a deep infection accurately may be lost. Despite understandable concern about inoculating an uninfected arthroplasty, arthrocentesis before antibiotic therapy usually is a sound practice, even if done adjacent to erythematous tissue. By contrast, a wound with either drainage or skin necrosis usually benefits from prompt surgical debridement, at which time reliable culture material may be obtained if antibiotic therapy has not been initiated.  

In the setting of early postoperative drainage without evidence of deep infection, and without erythema, purulence, or pain, where the surgeon does not otherwise suspect superficial or deep infection, immobilization and local wound care are warranted for a short period. If drainage does not stop or significantly decrease after a few days, operative debridement and closure should be considered. Observation times of 3 to 5 days and even up to 1 week have been advocated.  

Surgeons generally agree that a draining hemarthrosis should be evacuated. A nondraining hematoma in and of itself does not necessarily warrant evacuation. However, if the hematoma delays physical therapy, increases tension on the skin edges or closure, and exacerbates pain, surgical evacuation is defensible.  

Anterior knee pain has been significantly reduced since the introduction of patellofemoral resurfacing.  

Instability  

Instability after TKA is a cause of failure and the reason for 10% to 22% of revisions. Successful outcomes are obtained in many of these cases, but without identifying the cause of instability, the surgeon risks repeating the mistakes that led to the instability after the initial TKA.  

Three types of instability may occur after a TKA: extension instability, flexion instability, and genu recurvatum. It is important to understand the causes and treatments of each type of instability. Surgical treatment is largely aimed at restoring balanced flexion and extension gaps at the time of revision TKA. Selective use of constrained and rotating-hinge TKA designs is appropriate for subgroups of patients with instability.  

Osteolysis  

The most significant cause for late revision TKA is osteolysis, which occurs as the result of a foreign body response to particulate wear debris from the prosthetic joint. The ultimate result is loosening of the components. The incidence and extent of osteolysis after TKA are less than that after total hip arthroplasty. This complication has been noted with both cemented and cementless prostheses.  

Clinical symptoms, plain radiographs, and CT scanning have been used to study the extent and the natural history of osteolysis. Early in the disease process, patients may be asymptomatic. Most patients, however, present with symptoms of pain, swelling, and acute synovitis, with or without osteolysis on radiographs. Serial radiographs are then necessary to evaluate its progression.  

Vascular Injury  

Popliteal artery injury during TKA is rare but is potentially catastrophic. The injury may have acute or delayed presentation. Arterial thrombosis due to tourniquet application, arterial kinking during knee manipulation, and direct, sharp injury to the artery have been described. Direct, sharp arterial injury is believed to have a better prognosis than arterial thrombosis. Both hyperflexion and hyperextension of the knee during TKA can put the popliteal artery in danger. Prompt recognition of injury by the orthopedic surgeon and treatment by an experienced vascular surgeon are necessary to achieve a good outcome.  

Nerve Injury  

Both tibial and peroneal nerves may be injured during TKA. Preoperative flexion contracture or valgus deformity, and postoperative hematoma increase the risk of peroneal nerve injury. Conservative treatment is the first line of therapy, aimed primarily at preventing further injury. The knee and hip are flexed to 20° to 45°, and constrictive dressings are removed or loosened. Surgical exploration of the non-neurolytic nerve can be employed if no functional recovery is noted after 3 months from the onset of the injury.  

REFERENCES  

DEFINITION

- Accurate component positioning and limb alignment is one of the most critical steps in total knee arthroplasty (TKA). It has been shown that errors as small as 3 degrees can significantly affect the rate of loosening and the outcome of the TKA. The surgeon’s ability to determine component positioning accurately may be influenced by a number of factors, including patient positioning, obesity, variable anatomy, deformity, bone loss, and ligamentous anatomy.

- The main aim of computer-assisted TKA is to improve component positioning and limb alignment. Such improvement has been shown to increase longevity of the implant and decrease the need for revision surgery.

- The main function of navigation is to give the surgeon accurate information about the knee anatomy, limb alignment, and knee range of motion during the operation. The navigation system also gives real-time information as the operation proceeds. This dynamic intraoperative feedback regarding the orientation of bone cuts, soft tissue balancing, component positioning, limb alignment, and knee range of motion with the trial component in place should help the surgeon make the appropriate adjustments when needed.

- The navigation system makes more accurate information available for the surgeon, providing data that may help in making better decisions. It is still the surgeon, however, not the computer software, that decides how and where to make the cuts or release soft tissues to achieve the best implant position for the individual patient.

ANATOMY

- The success of TKA depends on proper alignment of the prosthesis in the coronal, sagittal, and horizontal planes. The surgical principle for proper alignment in the coronal plane is to restore the mechanical axis to neutral by placing the femoral and tibial components vertical to the mechanical axis of the limb.

- The mechanical axis is defined as a line connecting the center of the femoral head to the center of the ankle joint. The anatomic axis of the knee is described as the intersection of the lines drawn parallel to the long axis of the femur and tibia in the coronal plane and typically is between 5 and 7 degrees.

- In the standard intramedullary techniques, the anatomic axes are used as guides to estimate the mechanical axis; in navigation-assisted technique, however, the mechanical axes are determined and cuts are made perpendicular to those axes.

- When performing a TKA, the sagittal plane is kinematically important because most of the range of motion in the knee occurs in the sagittal plane. The degree of posterior slope of the proximal tibia has been used as the main indicator of proper sagittal alignment.

- The mechanical axis of the tibia on the sagittal plane can be determined in different ways. In one method, the midpoint of the tibial plateau is connected to the midpoint of the talus. In another, the midpoints of medial tibial plateau and the tibial plafond are connected in the sagittal plane. Either line can be used as the reference for measuring the tibial plateau slope.

- Rotational alignment of the implanted components is of the utmost importance in TKA. When a prosthesis is implanted with the incorrect amount of rotation, poor patellar tracking and anterior knee pain can result.

- The reference axis for rotational alignment of the femur remains controversial: the transepicondylar axis, the anteroposterior axis of Whiteside, and the posterior condylar axis have all been suggested. Each of these axes has flaws, however. For the rotational axis of the tibia, the medial third of the tibial tuberosity, as advocated by Insall, is approved by most surgeons.

- In navigation-assisted TKA, the reference for femoral rotation is the average rotational axis calculated by digitized transepicondylar and Whiteside lines, and the reference for tibial rotation is the digitized tibial anteroposterior axis.

- In navigation-assisted TKA with registration, the positions of anatomic landmarks and axes are digitized as references for instrument, bone cuts, and leg alignment. If a mistake in digitization occurs, the computer software usually will not progress. If a mistake is identified, the appropriate landmark should be re-registered.

SURGICAL MANAGEMENT

Preoperative Planning

- The most important step in preoperative evaluation is determining that the patient definitely does need the TKA.

- Preoperative knee radiographs should include a standing anteroposterior (AP) view, a lateral view, and a skyline view of the patella. A long-leg standing AP radiograph usually is unnecessary, because the navigation system can accurately determine the mechanical axis of the limb intraoperatively, even in the presence of previous deformity secondary to trauma or previous surgical procedures.

- In the standard technique, templates can be used to anticipate approximate component size and bone defects that would have to be treated intraoperatively. In the navigation technique, intraoperative templating is performed by digitization of different anatomic areas.

- The preoperative range of motion also is assessed by the navigation system, which is more accurate and helps the surgeon plan different cuts, including femoral flexion and tibial slope.

- Anesthesia, venous thromboembolism prophylaxis, and cardiovascular and internal medicine clearance are the same as that for standard TKA techniques.

Positioning

- The patient is placed supine on the operating table.

- A tourniquet is applied snugly to the upper thigh as far proximally as practical. In very obese patients, fat may be pulled distally from beneath the tourniquet, causing it to bulge.
from the distal edge of the tourniquet. This prevents it from migrating and ensures that the tourniquet is placed as proximal as possible.

- A transverse bar is placed on the table at a level just distal to the joint line. When the knee is fully flexed, the foot engages the bar and can, therefore, be maintained in the flexed position without the use of an assistant.
- The navigation system should be placed opposite the surgeon. Before starting with patient registration (ie, landmark digitization), it is recommended that the camera be brought in line with the knee joint so that all instruments can communicate easily with each other during the surgery (FIG 1).
- The system must be set up before the operation begins. All trackers and pointing tools should be initialized and validated, and the pointer tip should be calibrated.

**Approach**

- All standard and minimally invasive approaches for exposure of the knee joint can be applied and supported with the navigation system. The standard median parapatellar approach is described here.
- The most commonly used skin incision for primary TKA is an anterior midline incision.

---

**EXPOSURE**

- The incision is made with the knee in flexion to allow the subcutaneous tissue to fall sideways, which eases exposure.
- The skin incision should be long enough to avoid excessive skin tension during retraction, because that can lead to areas of skin necrosis.
- The medial skin flap should be kept as thick as possible by keeping the dissection just superficial to the extensor mechanism.
- The retinacular incision is extended proximally to the length of the quadriceps tendon, leaving a 3- to 4-mm cuff of tendon on the vastus medialis for later closure. The incision then is continued around the medial side of the patella, extending 3 to 4 cm onto the anteromedial surface of the tibia along the medial border of the patellar tendon.
- The medial side of the knee is exposed by elevating the anteromedial capsule subperiosteally and elevating the deep medial collateral ligament off the tibia to the posteromedial corner of the knee.
- The patella initially is everted to facilitate fat pad removal, but the remainder of the surgery is performed with the patella subluxated but not everted.
- The knee is flexed, and the anterior and posterior cruciate ligaments are removed.

---

**PLACEMENT OF TRACKER PINS**

- All anchoring pins are placed within the incision. Although this requires a slightly longer incision, it greatly simplifies pin insertion and minimizes damage to muscle. It also eliminates the potential for fractures around the pins, because they are not placed in diaphyseal bone.
- On the femur, the anchoring pin is positioned medially on the anterior surface just at the proximal aspect of the metaphysis (TECH FIG 1A). The tracker pin must be proximal enough to avoid interfering with the femoral cutting jigs and trial components. Medial placement allows

---

**FIG 1** The system should be placed opposite the surgeon to ensure instrument visibility.
The anchoring pin should be angled 30 degrees away from the mid-sagittal plane to avoid interfering with tibial cutting guides.

- On the tibia, the anchoring pin should be inserted across the medial tibial plateau parallel to the joint line in the sagittal plane to avoid collision with the tibial cutting guide and the keel of the implant. Placement in this location with the knee flexed also minimizes the risk of injury to the posterior vascular structures.

- For fixation, a pilot hole is predrilled with a 3.2-Amp drill. The pins should be driven bicortically using the insertion tool, and accurately measured for depth (TECH FIG 1B).

- Two trackers are used, one green and one blue. The green one is affixed to the femoral anchoring pin and the blue to the tibial anchoring pin. All femoral points are referenced off the green tracker and all tibial points off the blue tracker.

### DETERMINATION OF FEMORAL HEAD CENTER

- The center of the hip joint is identified by rotating the hip with both the hip and knee flexed. The software geometrically produces the center of femoral head within 1 mm of accuracy (TECH FIG 2). This is the most accurate way of identifying the center of rotation of the femoral head.

- During hip rotation, pelvic movement should be minimized. If the pelvis moves, an assistant should stabilize the pelvis and digitization should be repeated for location of the femoral head center.

### DISTAL FEMUR MAPPING

- The medial and lateral epicondyles and the knee center are digitized by placing the tip of the pointer at each point and pressing the Select button to record that point (TECH FIG 3A,B).

- For the femoral AP axis (Whiteside’s line), the axis of the pointer should be aligned with the most anterior point of the intercondylar groove (TECH FIG 3C,D). The Select button then is pressed for recording. The computer
software also averages the digitalized AP axis and transepicondylar axis, which can be used as an alternative reference for rotational alignment of the femoral component.

- Surface mapping of the distal femur is determined by digitization of the anterior cortex, the distal and posterior surfaces of the medial condyle, and the distal and posterior surfaces of the lateral condyle.
  - For each surface, the tip of the pointer is located on that surface and digitizing is begun by pressing the Select button. The pointer’s tip should be moved on the surface in a painting fashion.
  - The computer automatically progresses to the next reference point when the number of selected points is enough for mapping.
  - In anterior surface mapping, the least prominent anterior region, which usually is located along the lateral border of the femur, should be included in the mapping (TECH FIG 3E,F) to minimize oversizing of the femoral component.
  - When mapping the distal surface, the most distal aspect of the femoral condyle should be included (TECH FIG 3G,H).
  - During digitization, the pointer should never leave the surface.

PROXIMAL TIBIA MAPPING

- The surfaces of medial and lateral compartments of the tibia are mapped and registered in the computer (TECH FIG 4A,B). The lowest point on each condyle must be digitized.
  - The center of the tibial plateau and the anteroposterior axis also are digitized (TECH FIG 4C,D). The center of the insertion of the anterior cruciate ligament seems to be the most accurate landmark to use.
TECH FIG 4 • (continued) C. The AP axis of the tibia is identified. D. Corresponding navigation system screenshot.

DETERMINATION OF THE CENTER OF THE ANKLE

- The medial and lateral malleoli are digitized, and the computer determines the center of the ankle as a reference for the anatomic axis of the tibia and the mechanical axis of the limb (TECH FIG 5).

TECH FIG 5 • A. Digitizing the medial and lateral malleoli. B. Corresponding navigation system screenshot.

ASSESSMENT OF INITIAL ALIGNMENT AND DEFORMITY

- The trackers are attached to the anchoring pins, and the initial alignment, deformity, and range of motion are recorded. This information is extremely helpful in determining soft tissue releases that must be performed, bone cuts, and actual component selection.

MAKING THE BONE CUTS

- In this section we describe an anterior referencing system. Posterior referencing software also is available. The technique described here involves cutting the femur first, before the tibia, but the software is flexible and also allows tibia-first approaches.

- For all bone cuts, the green tracker will be located proximal to the blue tracker. For example, during all femoral cuts, the green tracker will be on the femoral anchoring pin and the blue tracker on the cutting jig. For all tibial cuts, the blue tracker will be on the anchoring pin and the green tracker on the cutting jig.

Making the Distal Femoral Cut

- The reference for the distal femoral cut resection level is the most distal point of the digitized condyles. The system calculates the length of perpendicular distance, from the most distal point to the resection plane, thereby establishing the depth of cut (TECH FIG 6A).

- The freehand horseshoe guide is put on the distal femoral surface and is fixed with two pins (TECH FIG 6B). Then the distal femoral cutting guide is assembled on the horseshoe guide while the tracker is attached to the tracker interface (TECH FIG 6C).

- In the reactive workflow, the software automatically opens the Resect Distal Femur dialog box (TECH FIG 6D). On the screen, the yellow disc visualizes the actual cutting block position. At the same time, flexion–extension alignment and medial and lateral resection depth are numerically displayed.

- The distal and lateral screws on the cutting device are adjusted until the cutting guide corresponds exactly to what the surgeon thinks is the most appropriate distal femoral resection for that patient (TECH FIG 6E).

- After fixation and position verification, the distal femur can be resected (TECH FIG 6F,G). For cut verification and documentation, a plane probe is held flush.
The system calculates the perpendicular distance, from the most distal point to the resection plane (depth of cut). The freehand horseshoe guide is fixed on the distal femoral surface. The distal femoral cutting guide is assembled on the horseshoe guide. In the Resect Distal Femur dialog box, the yellow disc is visualizing the actual cutting block position. The amount of femoral resection, flexion–extension, and varus–valgus orientation can be set up by the surgeon. Resection and verification of distal femoral cut. The femoral rotation guide and the blue tracker are placed on the distal femoral cut. Corresponding navigation system screenshot.

against the cut surface while the tracker is attached to it. Adjustments to this cut can be made as deemed necessary by the surgeon.

Making the Femoral Rotational Cut

- The blue tracker is attached to the rotation guide and placed on the distal femoral cut, and the Align Femoral Rotation menu is selected in reactive workflow. The yellow lines represent femoral rotation. Rotation is displayed numerically with respect to the average rotational axis, as well as the digitized AP and transepicondylar axes. The surgeon decides which rotational reference to use.
- The stylus is then attached to the rotational guide to prevent anterior notching (anterior referencing).
- Once proper alignment is obtained, the anterior cut is made. Again, the surgeon must determine the actual rotation.

The 4:1 cutting block is adjusted by the anterior cut surface and remaining femoral bone resections.
depth of this cut with respect to the anterior cortex. The plane probe can be used to check the rotational accuracy of this cut.

**Finishing Cuts on the Femur**
- The 4:1 cutting block is adjusted with the anterior cut surface, and the remaining femoral bone resections are completed (TECH FIG 8).
- Computer digitization has suggested a femoral size based on points chosen by the surgeon, but the size of the actual component chosen depends on many other factors that the surgeon must take into account when choosing the appropriate 4:1 cutting block.
  - If it is not clear which size to choose, it is best to err initially on a larger size.

**Making the Proximal Tibial Cut**
- The horseshoe guide is fixed on the proximal tibia using two pins (TECH FIG 9A–C). The tibial cutting guide is then assembled on the horseshoe guide while the green tracker is attached.
- The Resect Proximal Tibia interface is selected on the workflow. The yellow line on the screen is the actual cutting block position. The varus-valgus alignment, slope, and mediolateral resection depth are displayed numerically.
- The depth of resection, slope, and alignment are adjusted using adjusting screws, and then the cutting block is fixed to the tibial bone with two pins (TECH FIG 9D,E). Again, the surgeon decides on the depth, angle, and slope of the cut. The navigation system merely gives accurate numerical information to assist with this decision.
- The proximal tibia is cut, and the cutting surface is verified and documented using Resection Plane Probe with the tracker on it (TECH FIG 9F,G).

**Tibial Rotation**
- Tibial rotation is set using the appropriate tibial template assembled to the alignment handle and tracker. On the reactive workflow, the Tibial Rotation screen is selected. The yellow cross shows the rotational alignment of the handle, which also is shown numerically (TECH FIG 10).
- The tibial template should be aligned in the proper position, as determined by the surgeon, and pinned into the tibia.
Tibial Component Insertion

- At this stage, osteophytes along the medial or lateral margins of the knee can be removed to anatomic contours. The space for the tibial component keel is prepared using a power burr and impactor (TECH FIG 11A).

- If a PCL-substituting design is chosen, the intercondylar box is removed to accommodate the housing for the post and cam mechanism (TECH FIG 11B–F).

**TECH FIG 10** • The space for the tibial component keel is prepared using a power burr (A) and impactor (B).

**TECH FIG 11** • A. Preparation of the intercondylar box for PCL-substituting prosthesis. B. The overall limb alignment and knee motion are assessed while trackers are attached. C–F. Corresponding navigation system screenshots.

**LIMB ALIGNMENT AND SOFT TISSUE BALANCE**

- Trial components are placed, and the trackers are attached to the anchoring pins. Overall limb alignment and knee motion are assessed.

- Soft tissue then is selectively released according to the residual deformity present. (Specific details of how to balance the limb are beyond the scope of this chapter.)

**PATELLA**

- The patella is cut and balanced according to standard techniques.

**IMPLANTATION OF COMPONENTS AND CLOSURE**

- The technique described in this section uses standard techniques for final implantation of components and closure.

- We remove the anchoring pins before implanting the components. However, if the surgeon prefers, the anchoring pins can be left in place during implantation of components to check for accuracy of final component position and limb alignment.
**PEARLS AND PITFALLS**

| Tracker pins | - Loosening of the tracker pins at any point during the surgery indicates that the operation should be stopped. The loosened tracker pin is reinserted in a secure position, and registration and anatomic survey are performed again. |
| Hip center determination | - During hip movement to find the center of the hip, the pelvis should be stabilized; otherwise, the computer cannot locate the exact hip center. |
| Digitization | - During digitization, the pointer should never leave the surface. |
| Mid-range instability | - Mid-range instability often occurs in patients with severe valgus deformity. It can be avoided by releasing the posterior capsule if it is contracted, minimizing resection of the distal femur, and re-approximating the anatomic joint line. |
| Position of the femoral and tibial components in the sagittal plane must be adjusted based on existing deformity. | - In patients with hyperextension deformity: |
| | - Reduce bone cut off distal femur |
| | - Place the femoral component in slight flexion |
| | - In patients with flexion deformity |
| | - Increase bone cut off distal femur: |
| | - Avoid flexion of femoral component |
| Tibial slope | - To achieve more flexion in a particular patient, the tibial slope may be increased slightly. However, this may lead to anterior tibial translation and early posterior wear. Decrease in the tibial slope will lead to a decreased posterior joint space and decreased flexion. |

**POSTOPERATIVE CARE**

- Postoperative care after navigation TKA is the same as that after the standard techniques.
- Important perioperative interventions including prophylactic antibiotic, and deep vein thrombosis prophylaxis should be administered according to standard protocol. The limb is put in a compression bandage at the conclusion of the operation. Pain is controlled according to the selected pain management protocol.
- On the day of surgery, both passive and active range of motion is begun, and the patient sits on the side of the bed, stands with assistance, and walks if able. The importance of active and passive extension is emphasized to the patient.
- The expected length of stay in the hospital is 3 or 4 days.
  - On the second and third postoperative days, the patient transfers to and from the bed and chair, sits up in a chair, and ambulates with weight bearing as tolerated using a walker or crutches.
  - At the same time, the physical therapist starts daily rehabilitation programs to increase knee range of motion and to strengthen the operated leg.
  - On the third or fourth postoperative day, the patient should achieve flexion of at least 70 degrees and can be discharged with a walker or crutches.
  - In the first 2 weeks, a patient should be visited at home by a nurse and physical therapist to check the wound and continue rehabilitation.
  - At 2 weeks, sutures or staples are removed, and the patient should be sent to an outpatient physical therapy facility if needed.
  - The patient is then seen at the office at 6 weeks and 6 months after surgery and then routinely followed every 3 years.

**OUTCOMES**

- Total knee arthroplasty has shown results that are both durable and consistent, with over 90% survivorship into the second decade. This long-term success has been related to patient characteristics and the accuracy with which the prosthesis is implanted.
- The navigation system, unlike standard technique, makes it possible to significantly improve the mechanical alignment of the limb, sagittal and frontal alignment of the femoral and tibial components, and knee range of motion without increased short-term complications. This more accurate and precise positioning and alignment of the components should reduce the rate of long-term complications and revisions.

**REFERENCES**

DEFINITION
- The number of revision TKA procedures performed is projected to increase at an annual rate of 19.3%.8
- Femoral bone defects are uncommon in primary TKA but are very common in revision knee surgery.
- Modular femoral augments are useful for moderate-sized bony defects, allowing the surgeon to maximize bone–prosthesis contact while restoring the joint line or posterior condylar offset.
- Improvements in prosthesis design and biomaterials have increased the usefulness and versatility of metal augments in addressing larger bone defects.
- A systematic approach to preoperative planning, intraoperative evaluation, and reconstruction is essential in addressing femoral defects using augments.

ANATOMY
- The most common form of bone defect encountered at the time of revision surgery is bone loss from the distal and posterior femur (Table 1).
- Aside from “filling the defect,” it is important to restore the femorotibial joint line and the posterior condylar offset. Significant alterations in either or both will be detrimental to the function of the prosthesis.
- The joint line typically lies 25 mm distal to the femoral epicondyles, and the posterior femoral condyles are offset an average of 25.8 mm from the posterior cortex of the femur.2

PATHOGENESIS
- In unoperated knees, bone loss on the femoral side can be caused by previous osteochondral defects, avascular necrosis,
severe valgus or varus deformity, posttraumatic arthritis, and Charcot arthropathy (FIG 1A).

- During revision surgery, osteolysis secondary to wear debris and bone loss secondary to removal of well-fixed components or a cement mantle are the most common causes of femoral bone defects (FIG 1B).
- Rarely, earlier trauma resulting in severe angular deformity may require the use of augments for joint reconstruction and restoration of limb alignment.

NATURAL HISTORY

- Untreated bone defects in the native knee can lead to progressive joint collapse, ligamentous laxity, and progressive bone loss.
- Osteolytic lesions caused by wear debris can progress and lead to loss of implant support and eventual component loosening.
- Intraoperative mismanagement of defects can lead to suboptimal fixation, significant alterations in knee kinematics, instability, and early implant failure.

PATIENT HISTORY AND PHYSICAL FINDINGS

- A complete history and physical examination must be performed before any revision knee surgery is undertaken. The details of the index arthroplasty with regard to pain relief and the interval to failure should be recorded. In addition, problems during the postoperative period such as falls or operative wound complications should be probed.
- Patients with loose femoral components often present with painful TKAs. Pain often occurs at start-up, arising from the seated position, and with stair climbing. These patients often may complain of swelling and effusions within the knees.
- An AP radiograph of the pelvis and a careful back and hip examination should be performed to rule out coexistent spinal or hip disorder as the cause of the patient’s knee pain.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Plain radiographs of the knee, including standing AP, lateral, and Merchant views of the affected knee, should be reviewed. For patients with deformity, the entire length of the affected bone should be visualized.

- In revision cases, serial radiographs may help assess the progression of osteolysis, radiolucent lines, and implant migration.
- CT scans of the knee permit assessment of component rotation and can assess the size and location of osteolysis more accurately.4 Recently, MRI also has been shown to be effective in quantifying osteolytic defects.9
- Blood studies, including a complete blood count with differential, sedimentation rate, and C-reactive protein, should be obtained to rule out infection.
- Nuclear medicine studies including bone scan (to detect a loose prosthesis) and indium and sulfur colloid scans (to detect the presence of infection) also can be helpful in the preoperative workup.
- Aspiration should be done when there is any suspicion of infection. The synovial fluid should be evaluated and cultured for the presence of microorganisms.

DIFFERENTIAL DIAGNOSIS

- Infection
- Arthritis of the hip and spine
- Flexion instability
- Patellar maltracking and extensor mechanism dysfunction
- Tibial component loosening
- Periprosthetic fractures

NONOPERATIVE MANAGEMENT

- Unless the patient has obvious signs of component malpositioning, loosening, fracture, or infection, a trial of conservative treatment aimed at strengthening the quadriceps musculature with emphasis on the vastus medialis oblique muscle should be the cornerstone of nonoperative treatment.
- Patients who have evidence of early osteolysis on plain radiographs but have no clinical symptoms or pain should be encouraged to obtain serial radiographs annually to check for progression of the lesion(s).
- No consensus has been reached regarding when it is appropriate to revise or perform bone grafting in an asymptomatic knee with radiographic evidence of osteolysis.
PART 3  ADULT RECONSTRUCTION • SECTION III  KNEE RECONSTRUCTION

SURGICAL MANAGEMENT

- A systematic approach is required to reconstruct bone defects successfully during revision surgery.

Preoperative Planning

- Thorough preoperative planning is the key to a successful reconstruction.
- Review of radiographs and CT scans and careful templating allow anticipation of problems that could be encountered during surgery (Fig 2A,B).
- Most bone loss can be addressed by the use of metal augments and a long-stem prosthesis (Fig 2C).
- For larger osteolytic lesions, special wedges, femoral heads, and allografts must be ordered in advance so they are available during reconstruction.
- In all cases of revision, stemmed and constrained implants (or sometimes a hinged prosthesis) must be considered and must be available.

Positioning

- The standard position for patients undergoing revision TKA is supine.

- Care is taken to drape out a wide surgical field in case a more extensile approach is necessary. A sterile tourniquet applied on the surgical field may be helpful.

Approach

- The knee is approached via the standard medial parapatellar approach.
- Protection of the patellar tendon during this phase of the operation is crucial.
- An extensive synovectomy and debridement of the medial and lateral gutters are critical for decompression of the joint.
- The patella usually is not everted during revision TKA.
- In knees with severe ankylosis, techniques such as the quadriceps snip, lateral release, and tibial tubercle osteotomy are helpful for exposure. The surgeon must know the implications of each of these releases and repair or reconstruct them properly at the end of the procedure.
- The bone defect is addressed by the use of cement (smaller lesions), metal augments, or structural grafts. The critical issues are to restore joint line, achieve appropriate alignment, and attain ligamentous balancing. Reconstruction also aims at restoring a stable platform for positioning and fixation of the components.

Positioning

- The standard position for patients undergoing revision TKA is supine.

Metal Augments

- Modular metal augments allow for restoration of distal, posterior, and even metaphyseal femoral defects.
- For most systems, the largest femoral augments allow for restoration of 8 to 10 mm of bone defect. The use of cemented stacked augments for filling defects up to 30 mm has been reported.
- Most revision systems have intramedullary systems that allow bone cuts to be made relative to a press-fit intramedullary rod.
- The distal femoral cut is freshened to provide a stable platform for the new prosthesis.
- Next, the size of the femoral component is selected. Preoperative templating can give clues to the proper component size. Traditionally, the femoral component is upsized to better fill the flexion gap (Tech Fig 1A).
- Determining proper femoral component rotation is critical to a successful reconstruction. The femoral component should be set parallel to the transepicondylar axis of the femur (Tech Fig 1B). Other secondary guides include the proximal tibia and the femoral intercondylar line.
- Malrotation of the femoral component also can exaggerate the severity of bone loss.
- The rest of the reconstruction varies according to the revision knee system being used, but should follow a systematic approach. In some systems, the trial components

FIG 2 • A, B. AP and lateral radiographs of the knee before revision surgery. Large osteolytic defects involving both the femur and the tibia are visible. Careful preoperative planning is required to be able to address bone loss encountered at the time of arthroplasty. C. Most cases of knee revision with bone loss can be addressed with the use of a long-stem prosthesis and metal augments.
Chapter 21  REVISION TKA WITH FEMORAL BONE LOSS: METAL AUGMENTS

TECH FIG 1 • A. Sizing the femoral component is an important part of the revision process. B. Assessing the appropriate rotation using transepicondylar axis and Whiteside’s line. Note the distortion of the posterior condylar line as a result of bone loss. C. Some implants have trials with slots, which allows for more precise sizing and preparation for modular augments. D. Femoral trial with augments and stem in place.

have slots that allow cuts to be made for more precise fitting of the modular augment (TECH FIG 1C).
- A stemmed trial femoral component with the necessary augments is assembled and inserted. Trialing should focus on the overall stability of the knee in extension and flexion, and also on patellofemoral tracking (TECH FIG 1D).
- The definitive prosthesis is assembled and cemented into place in the standard fashion.

BONE CEMENT
- Indicated for use in small, preferably contained, bony defects up to 5 mm in depth
- Limitations: cannot be used for uncontained defects, and does not restore bone stock
- Following removal of the existing prosthesis, all surfaces are thoroughly débrided. There is a membrane that often forms between the old bone–cement interface. Areas of bony sclerosis should be débrided to punctate bleeding with the aid of a high-speed burr.
- The femur is prepared with the revision instrumentation specific to the implant system, paying attention to joint line restoration, rotation, and restoration of the posterior condylar offset. The use of stemmed implants allows for distribution of joint stresses and almost always is required in cases of revision surgery with bone loss.
- The new femoral component is cemented into place separately, and the cement is allowed to harden under direct vision.

MORSELIZED AUTOGRRAFT OR ALLOGRAFT
- Indicated for use in larger contained defects, especially in younger patients. The main advantage of this technique is that it allows for restoration of bone stock.
- Limitations: cannot be used for uncontained defects, and does not restore a stable platform capable of supporting the prosthesis
- Using a curette or a high-speed burr, the host bone is débrided to create a favorable environment for graft incorporation.
  - Visible defects are packed with morselized auto- or allograft.
  - A bone tamp may be used to pack the bone chips tightly.
- Prepare the femur using the revision instrumentation particular to the system being used.
- Once the femur is prepared, insert a stemmed trial femoral component, with or without wedges, onto the femur.
- Before final impaction of the trial component, tightly pack the bone chips around the stems and the posterior condyles. Impacting the trial prosthesis into place will effectively shape the new distal femur.
- The new stemmed femoral component is cemented separately to minimize the chance of component malposition.
### Structural Allografts (Femoral Hemicondyle)

- Structural allografts are indicated for large, uncontained defects involving one femoral condyle. The attachments of the collateral ligaments are preserved by a thin shell of bone following removal of the femoral implant.
- The host bone–allograft interface is prepared as previously described.
- Gently, using a hemispherical acetabular reamer, the bony defect is reamed to accept a femoral head (TECH FIG 2A).
- Using the corresponding female resurfacing reamer, a femoral head allograft is reamed to remove all cartilaginous debris (TECH FIG 2B).
- The femoral head is coupled to the bony defect and secured using two threaded Steinmann pins inserted from proximal to distal (TECH FIG 2C).
- The distal femur then is prepared using the instrumentation particular to the system being used.
- The femoral head allograft is fixed to the host bone using 4.5-mm short-thread cancellous screws inserted from proximal to distal (TECH FIG 2D).
- Finally, a stemmed femoral component is cemented into place.

### Distal Femoral Allograft

- Indicated for massive osteolytic defects involving both distal condyles and distal femoral metaphysis. It allows for restoration of bone stock while preserving the collateral ligament insertions.
- In cases in which a distal femoral allograft may be required, preoperative sizing of the host femur and the allograft is crucial.
- Comparing radiographs of the allograft to the host femur (may size against an unoperated side if available) improves fit and decreases the chances of mismatch.
- The native femur is prepared to accept the allograft by carefully preserving the collateral ligament attachments (TECH FIG 3A).
- The allograft is then shaped to allow for intussusception (bone within bone) into the native femur. It is important to obtain a secure fit of the allograft during this step (TECH FIG 3B).
- Using traditional distal femoral cutting guides, the femur is prepared to accept a stemmed prosthesis (TECH FIG 3C–E).
- Demineralized bone matrix is used to line the host–allograft interface. This allows the filling of gaps and also provides a barrier against cement intrusion (TECH FIG 3F).
- A stemmed femoral implant is cemented into place (TECH FIG 3G,H).
**TECH FIG 3** • A. Severe bone loss encountered during surgery. Because the collateral ligaments were still intact, use of structural allograft to reconstitute bone was deemed appropriate. B. The allograft is cut to the approximate size needed to fit the defect. C–E. The rest of the cuts are performed using standard instruments to obtain a well-shaped structural graft. The prepared graft is produced to fit the defect exactly. F. Demineralized bone matrix can be used in the interface between allograft and host. G,H. The long stem implant is then cemented over the allograft.

The host bone should be thoroughly débrided to optimize the interface between the native bone and the allograft bone or cement. Restoration of the joint line and the posterior condylar offset is crucial to the overall success of the revision process. Failure to restore posterior offset can lead to motion loss.\(^6\) When using metallic augments, the decision to use distal femoral augments is made early in the procedure. Revision instrumentation will key off these augments for subsequent bone cuts. When using distal femoral allografts, prepare the allograft by first removing the epicondyles and making a provisional cut on the anterior cortex of the allograft. This will allow the allograft to be impacted into the host bone.

Each component should be cemented separately to prevent inadvertent changes in component position. During final impaction of the definitive prosthesis, pay attention to its position in relation to the posterior condylar offset. Restoration of the joint line and the posterior condylar offset is crucial to the overall success of the revision. An intraoperative radiograph can help assess the overall alignment of the implants and their position in relation to the tibiofemoral joint. Using a marking pen, trace out the anterior phalange of the revision femoral component once a satisfactory trial of all the components. This tracing will provide a guide to the depth of seating for the definitive prosthesis.

Early motion is instituted for most patients using a continuous passive motion (CPM) machine set from 0 to 60 degrees immediately following surgery. For patients who have had extensive procedures, a well-padded Robert Jones dressing is applied following the operation. Immobilization is maintained for 24 to 48 hours. Following revision TKA, patients usually are allowed to bear weight as tolerated on the prosthesis. Alterations of weight-bearing status and limitations on knee flexion generally result from other procedures performed at the time of arthroplasty, such as tibial tubercle osteotomy, quadriceps snip, or V-Y turn-down.

Overall, the survivorship of revision femoral components using metal wedges with or without structural augments is 79.4% at 8 years.\(^1\) For knees with small, contained cavitary defects requiring only cement or morselized graft, the 10-year survivorship approaches that of primary knee arthroplasty.\(^7\) Modular femoral augments used for reconstruction of type II defects have an 11-year survival rate of 92%. It is not uncommon to see nonprogressive radiolucent lines surrounding metallic augments.\(^8\) Femoral revisions augmented with structural allografts have a 10-year survival rate of 75%.\(^3\)

**COMPLICATIONS**

- Traditional complications following revision TKA include infection, wound complications, and loosening.
- Patellar maltracking and extensor mechanism dysfunction also can occur, especially if there is component malrotation.
- Knee instability can result from an imbalance in the flexion and extension gaps.
- Resorption of large structural allografts leading to subsequent implant loosening has been described.

**REFERENCES**

Bone loss and indications for the use of metallic augments in revision total knee arthroplasty (TKA) usually are guided by classification of the bony defect.

Several classification systems have been developed and introduced that describe and quantify proximal tibial bone loss with the intent of guiding preoperative planning and intraoperative treatment and aid in forming a prognosis postoperatively.

Classification systems assess the bony defect in terms of size, location, presence or loss of cortical containment, and symmetry or disparity across the tibial plateau. One of the most widely used systems is the Anderson Orthopaedic Research Institute (AORI) bone defect classification system.

The AORI bone defect classification system divides bone loss of the distal femur or the proximal tibia into three types, based on the radiographic status of the metaphyseal bone.

- Distal femoral metaphyseal defects are graded as FI, FII, or FIII.
- Proximal tibial metaphyseal defects are graded as TI, TII, or TIII.
- The metaphyseal region of the proximal tibia is defined as the bone cephalad to the tibial tubercle.

Type I defects of the proximal tibia have intact metaphyseal bone with no component subsidence or loss of the primarily reconstructed joint line.

- Minor defects may be present that will not compromise the stability of the tibial component at the time of revision surgery; in such cases, primary type reconstruction components may potentially be used.
- Type II defects of the proximal tibia have damaged metaphyseal bone with component subsidence or joint line alteration due to loss of metaphyseal bone.

- Bone loss in type II defects can involve either the lateral or, more commonly, the medial tibial plateau as well as the entire proximal tibia.
- Defect reconstruction with cement, augments, or, possibly, bone grafting is required to reestablish the joint line at an appropriate level, and revision stemmed components usually are required.

Type III defects of the proximal tibia have deficiency of the proximal metaphyseal bone that involves a major segment of the proximal tibia.

- This type of defect may involve the tibial tubercle, with resulting patellar tendon detachment and loss of extensor mechanism function.
- The medial collateral ligament also may be detached or functionally incompetent (ie, pseudo-laxity) as a result of bony deficiency.
- The broad insertion of the medial collateral ligament on the proximal medial metaphysis of the tibia renders incompetence or frank loss of attachment due to tibial bone loss less likely as compared to femoral condylar bone loss, where the origin of the medial collateral has a much smaller footprint or area of attachment to the medial epicondyle.
- Defect reconstruction with augments and structural bone graft is required to fill the bony deficiency. Long-stemmed revision implants are required, including hinged modular revision components.

- A custom component rarely is required because of the availability of modular oncology or limb-preserving systems.

In summary, proximal tibial bone defects are classified as intact, or type I (TI); damaged, or type II (TII); and deficient, or type III (TIII).

- By definition, the use of metallic augments is restricted to type TII or TIII defects. TIII defects with frank bony deficiency often require bulk structural allograft, either alone or in combination with metallic augmentation.
- The major indication for isolated metallic augmentation is a type II tibial bone defect.

The native tibial plateau has a 3-degree varus slope in the coronal plane relative to the mechanical and anatomic axes of the tibia, to match the 3-degree valgus slope of the femoral condyles.

- The distal femur has a 3-degree valgus slope relative to its mechanical axis and a 9-degree valgus slope relative to its anatomic axis in the coronal plane.
- In the sagittal plane, the proximal tibia has a posterior slope of 9 to 10 degrees on average, with a range of 4 to 12 degrees. The medial tibial plateau is mildly concave, and the lateral tibial plateau is mildly convex.

About 60% of ground reaction forces are transmitted through the medial tibial plateau; the remaining 40% are transmitted through the lateral plateau.

- The trabecular bone of the proximal tibia is densest in its most proximal 1 cm and is responsible for load transmission.
- The strength and stiffness of the proximal tibial bone are dictated by trabecular architecture and bone density, with the most dense area being central in each plateau.

- The bone also is more dense between the plateaus under the tibial spine and decreases in density toward the periphery of the plateau.
- The subchondral, epiphyseal, and metaphyseal bone is relatively denser in the medial tibial plateau due to higher load transmission compared to the lateral tibial plateau.
- The tip of the fibular head is approximately 1 cm below the surface of the lateral tibial plateau.
The tibial tubercle is 25 to 40 mm below the joint surface, and the average insertion point of the patellar tendon is 29 mm distal to the tibial plateau.

The patella tendon averages 44 mm in length and ranges from 33 to 53 mm in length. Therefore, the distal pole of the patella averages 15 mm above the joint surface and ranges from 12 to 16 mm.

The fibular head is the most commonly used bony reference for joint line restoration in the revision TKA setting.

Improved outcomes are noted if the joint line is elevated less than 8 to 10 mm. Pre- and postoperative radiographs of the primary procedure allow the most accurate determination of the postarthroplasty joint line.

Blood supply to the proximal tibia is both endosteal and periosteal (FIG 1A). The endosteal blood is supplied via a nutrient artery branching from the posterior tibial artery that enters the tibia posteriorly and distal to the soleal line. The proximal tibial periosteal blood is supplied by the medial and lateral inferior genicular arteries as well as the anterior tibial recurrent artery. The medial and lateral inferior genicular arteries arise from the popliteal artery and pass deep to the collateral ligaments to supply the medial and posterolateral periosteum of the proximal tibia.

The anterior recurrent tibial artery is an ascending branch that arises from the anterior tibial artery just after it passes through the proximal tibiofibular interosseous membrane and supplies the anterolateral periosteum of the proximal tibia. All of these vessels also contribute to the anterior anastomotic peripatellar ring.

Neurovascular injury during primary and revision TKA is rare. The popliteal neurovascular bundle is at greatest risk during proximal tibial resection.

These vessels are 3 to 12 mm posterior to the articular surface of the tibia when the leg is extended and 6 to 15 mm posterior when the knee is flexed to 90 degrees. At the level of the tibial resection the distance is approximately 2 cm posterior to the cut surface.

The popliteal artery and vein are anterior to the tibial nerve at this level.

Most revisions do not put the tibial artery trifurcation at risk unless more than 30 mm of proximal tibia is resected, which occurs when a tumor prosthesis is utilized for proximal tibia replacement.

Most neurovascular injuries during primary and revision TKA result from tourniquet use in the patient with peripheral vascular disease. The proximal tibial anatomy of the TKA requiring revision total knee arthroplasty is highly variable (FIG 1B,C).

Component subsidence, osteolysis, fracture, and infection can alter the usual post-arthroplasty anatomy of the proximal tibia.

Pre- and postoperative radiographs of the primary procedure can be invaluable during preoperative planning of the revision surgery to determine actual bone loss and true change in component position.

The type of component noted on the postoperative primary radiographs can be helpful in determining the amount of bone that was originally resected from the proximal tibia.

Cruciate-retaining implants typically are cut with 3 to 7 degrees of posterior slope in the proximal tibial resection, whereas cruciate-sacrificing and cruciate-substituting or posterior stabilized implants typically have 0 degrees of posterior slope.

Consequently, in the revision setting where posterior stabilized or “super stabilized” or “total stabilized” type components are used, additional anterior resection of the tibial plateau may be required to restore neutral slope.

Some revision systems call for a slight amount of slope to match the design of the stemmed tray, and the proximal tibial should be resected accordingly.

Bone defect classification schemes as outlined earlier for damaged or deficient metaphyseal tibial bone can greatly aid in understanding the pre-revision anatomy.

PATHOGENESIS

Multiple causes may lead to failure of the primary TKA, including aseptic loosening, deep infection, flexion instability, complex regional pain syndrome, malalignment, postoperative stiffness, and extensor mechanism complications.

Proximal tibial bone loss in primary total knee failure can be attributed to the following factors: implant malalignment
Septic loosening is the result of bacterial infection of the knee.

- Bone insufficiency or osteopenia from stress shielding, osteolysis, or osteonecrosis can be underlying factors contributing to pre- or intraoperative bone loss.
- The quantity of osteolysis is affected by implant design and the quality of polyethylene, as well as host response to particulate debris.
- Disuse osteopenia may contribute to massive proximal tibial bone loss in the presence of periprosthetic fracture.
- Component loosening and resultant implant failure occur primarily via two common routes: aseptic, due to osteolysis; and septic, due to bacterial infection.
- Osteolysis of the proximal tibial bone is a result of polyethylene particulate debris from wear at the bearing interface as well as “backside” wear.
- Backside wear results from micromotion between the polyethylene insert and the modular tibial tray.
- Somewhere on the order of billions of submicron polyethylene particles per year can be generated at the bearing surface.
- These particles generate histiocytic and macrophage response, where intercellular signaling pathways are activated that promote osteoclast activity and bone resorption.
- Osteolytic lesions are either focal or expansile, depending on the submicron particle burden as well as the host response to the particles.
- The process begins in areas of soft or exposed bone that are subject to intra-articular synovial fluid pressure.
- Debris-filled synovial fluid and resultant areas of osteolysis follow the paths of least resistance around tibial component of the implant.
- Susceptible areas include uncovered bone of the tibial plateau, ie, areas covered by neither the component nor cement.
- Screw holes and areas on the undersurface of the tibial tray that lack the bony ongrowth surface of a press-fit tibial component also offer pathways to the metaphyseal bone.
- As mentioned previously, the metaphyseal bone is stronger centrally and more resistant to significant osteolysis; however, the periphery is weaker and more prone to osteolysis.
- As osteolysis progresses, the tibial component loses its bony support, and a radiolucent line forms between the component itself or the component cement mantle and the underlying metaphyseal bone.
- The tibial component is aseptically loose when the radiolucent line is circumferential and no direct bony support remains.
- Both expansile osteolysis and component loosening can lead to component subsidence, usually into a varus position.
- The medial tibial plateau is dimensionally larger than the lateral tibial plateau and potentially has more exposed cancellous bone when symmetrical tibial components are utilized.
- Septic loosening is the result of bacterial infection of the knee.
- Classically, the organism most commonly isolated from the knee was *Staphylococcus aureus*; however, more recent studies suggest that *Staphylococcus epidermidis* may be equally common, although less virulent. Bacterial infection occurs through one of several routes.
- The knee may be contaminated at the time of implantation, although this happens in less than 0.5% of cases.

Hematogenous inoculation of the joint with bacteria also may occur in the face of a previously well-functioning prosthesis.

Dental work causes bacteremia 100% of the time, and other procedures such as gastroesophageal endoscopy and colonoscopy all introduce potential for bacteremia and late hematogenous spread to the implanted knee.

All surgical procedures put a prosthesis at increased risk for infection.

Less virulent organisms may not lead to significant bone loss intrinsically, but more virulent organisms often result in a loose component.

A third route of infection is direct contamination of the knee by trauma, ie, traumatic arthrotomy.

Most prosthetic infections are treated with two-stage revision arthroplasty of the knee, in which either a static antibiotic spacer or a dynamic articulated type of spacer is used for the first stage of the revision.

Preformed antibiotic-loaded polymethylmethacrylate spacers are commercially available, but the concentration of antibiotic in the cement is predetermined by the manufacturer.

In some instances, the concentration in a preformed spacer may not be sufficient to overcome a virulent organism or to meet the preference of the surgeon.

Articulated spacer molds allow the surgeon to select the quantity and type of antibiotic to be loaded into the cement spacer.

The second stage of the revision takes place once serum inflammatory markers have returned to within normal limits and the patient has responded clinically to both the antibiotics in the spacer and those given intravenously.

The time between the first and second stage of the revision TKA for infection is typically 8 to 12 weeks.

Implantation of a well-fixed primary component leads to potentially significant bone loss when it is removed from an osteopenic tibial metaphysis.

Occasionally a static antibiotic spacer may subside or displace in the joint between the revision stages, further contributing to bone loss.

A comparison study of static and articulated spacers showed greater bone loss with static spacers than with articulated spacers.

Maximizing bone coverage with either type of spacer appears to preserve bone stock.

The AORI classification also applies to bone loss, either present or anticipated, at the second stage of the staged revision knee arthroplasty.

**NATURAL HISTORY**

- The osteolytic process is clinically silent until the prosthesis loosens.
- A loose prosthesis causes startup pain as well as cyclic pain with loading, provided that fracture or gross displacement of the component has not occurred.
- The pain may decrease with weight bearing as the component reseats itself and motion at the bone implant interface decreases.
- Expansile osteolysis and component subsidence or proximal metaphyseal fracture may result in gross lower extremity deformity, usually varus, and occasionally may also present with hyperextension if the component subsides into an anteriorly sloped position.
Radiographic examinations of the implanted knee should be performed at regular intervals to detect the presence or progression of osteolysis.

The presence of osteolysis and its rate of progression depend on the polyethylene type and processing of the implant as well as the host response to particulate debris.

Many modular systems that use polyethylene inserts gamma-irradiated in air demonstrate accelerated wear patterns with high particle production.

Many of these implants demonstrated osteolysis within 36 months of implantation.17

Specific timeframes for aseptic component loosening are difficult to predict globally, because there are many contributing host and implant variables.

Septic failure of TKA is noted in the perioperative period in 0.5% of patients.

Delayed hematogenous infection occurs in 1% to 2% of TKAs over the lifetime of the implant.20

Infection must be ruled out in all painful TKAs.

Differentiation between septic and aseptic loosening of the tibial component is of paramount importance, because the management of each type is different, and a misdiagnosis can result in loss of limb.

PATIENT HISTORY AND PHYSICAL FINDINGS

The patient history and physical findings are centered around differentiating between septic and aseptic loosening, the amount of bony destruction and the ligamentous insufficiency present, and the resultant instability of the knee.

Patients with symptomatic osteolysis or loosening of the tibial component usually describe gradual onset of pain that is worse with startup type of activities such as arising from the bed or getting out of a chair or a vehicle.

They also commonly describe increased pain with the first steps of ambulation, which may decrease as the component settles into the remaining bony mantle of the proximal tibia.

There is less or no pain with rest.

The infected TKA will cause pain at rest, and patients who have deep infection may describe a temporal pain pattern with increasing or steady pain from the day of surgery to the day of clinical evaluation with no remittance.

Late hematogenous infection presents with sudden onset of pain in a previously well-functioning prosthesis.

An acute knee effusion and loss of range of motion and stiffness also may present in this setting.

Complete neurovascular examination of the affected extremity should be carried out, along with focal examination of the knee.

Visual inspection for edema and erythema is pertinent in the face of infection.

Range of motion and patellar tracking should be evaluated along with ligamentous stability and overall limb alignment. A difference between active and passive extension demonstrates extension lag versus flexion–contracture.

Specific attention should be directed toward evaluating the functional status of the medial collateral and posterior cruciate ligaments in a knee with cruciate-retaining implants.

A quadriceps active test and posterior sag signs are useful to evaluate the functional status of the posterior cruciate ligament (PCL).

Varus and valgus stress tests in extension, in midflexion, and at 90 degrees of flexion are useful to evaluate the collateral ligaments for instability. If present, instability may be graded according to laxity.

Anterior and posterior drawer tests evaluate status of the PCL, conformity of the bearing surface, and proper function of cam–post mechanism as well as flexion gap.

If significant posterior subluxation is seen on posterior sag testing, it suggests a nonfunctioning PCL in a cruciate-retaining TKA.

The quadriceps active test also demonstrates failure of the PCL or of the cam–post mechanism in a posterior stabilized implant.

IMAGING AND OTHER DIAGNOSTIC STUDIES

Plain film radiographic views of the affected knee are required (FIG 2).

Multiple orthogonal views, including oblique views, may illustrate areas of bone loss more fully.

The skyline view, while part of a complete radiographic analysis, does not allow visualization of the tibial component.

Weight-bearing anteroposterior and lateral views can be helpful to load the knee and show the component position of maximum subsidence as well as resultant limb.

It is important to obtain tangential views to properly align the bone implant interface with the beam of the radiograph.

If plain radiographs are thought to underrepresent the true volume of osteolysis, consideration may be given to CT with metal suppression.25

Conversely, if there is doubt regarding actual loosening of the component, technetium-99m bone scanning can illustrate areas of increased bone turnover that may indicate possible looseness of the tibial component.

In cases in which infection is suspected, the bone scan can be compared to an indium-111–tagged white blood cell scan.

Aspiration of the knee joint with culture of a definitive organism is the ideal confirmation of an infected TKA.
DIFFERENTIAL DIAGNOSIS
- Osteolysis
- Infection
- Tibial component loosening
- Tibial component subsidence
- Periprosthetic proximal tibial fracture

NONOPERATIVE MANAGEMENT
- Nonoperative management of a loose tibial component due to osteolysis with or without subsidence and fracture should be considered only if the revision procedure will place the patient’s survival in jeopardy or make their quality of life worse than it was at presentation.
- The same caution applies to patients with indolent infections. Virulent organisms can cause bacteremia and sepsis. Emergent surgical explantation of the components may be required to prevent septic shock and death.

SURGICAL MANAGEMENT
- Ideally, the patient is medically optimized for revision knee surgery and all medical comorbidities have been addressed before the surgery.
  - Risk stratification should be performed by medical subspecialists based on the patient’s medical history and on the recommendations of a general medical doctor.
  - The patient should be fully informed of the risks compared to the benefits of the revision total knee surgery and of the bone loss management plan.
- Intraoperatively, the need for metallic augmentation is confirmed by segmental defects, defects that involve more than a quarter of the cortical rim, or defects that will result in less than 60% direct bony support of the revision component confirm.17

Preoperative Planning
- Evaluating the component position and classifying the present bone loss on plain films is the cornerstone of preoperative planning.
  - Metaphyseal bone quality should be evaluated and intraoperative bone loss anticipated.
  - Templating should be carried out with the focus on restoring the joint line and filling the bony defect. The broad insertion of the medial collateral ligament presents an issue only for severe bone defect unless it is found to be incompetent on the preoperative physical examination. Close attention should be given to the planned level of resection and its relation to the insertion of the extensor mechanism. Wedge augments should be avoided if possible, but are indicated if needed to spare bone around the tibial tubercle.
  - The condition of the patient’s skin should be carefully evaluated in the physical examination.
- All previous skin incision and their age should be noted.
- An anterior midline incision is preferred, but it may be necessary to use the most lateral incision to protect the patient from skin necrosis in areas between incisions. A 7-cm skin bridge should be maintained between all incisions if at all possible.
- Patients with significant potential for necrosis may need to undergo a “sham” procedure to ensure the skin is viable.28 This involves an incision just through the skin without involving the extensor mechanism to verify healing potential.
- The existing implant in the knee should be identified, and the operative reports of the previous surgery should be obtained prior to surgery.

Positioning
- The patient is positioned supine on the operating room table.
- A well-padded, non-sterile tourniquet is placed as proximally as possible on the operative lower extremity. All bony prominences are well padded.
- A bump may be placed under the hip and pelvis on the operative extremity side, depending on the surgeon’s preference.
- The nonoperative extremity is secured to the table.
- A bean bag, horizontal post, or leg-holding device such as an Alvarado leg positioner may be used to hold the leg in a flexed position during the procedure.

APPROACH
- A standard midline incision with a medial parapatellar arthrotomy is ideal. The skin is incised from 5 cm (or more, if necessary) proximal to the patella. The incision is centered over the patella and patellar tendon to the tibial tubercle (TECH FIG 1A).
  - Some surgeons prefer to bring the distal half of the incision slightly medially so that it terminates at the medial edge of the tibial tubercle. Preference is always given to the previous skin incision.
  - The anterior midline incision is carried down to the extensor mechanism, and full-thickness flaps are elevated both medially and laterally (TECH FIG 1B).
- The medial flap usually must only be carried medially to the distal aspect of the vastus medialis obliquus muscle.
- Laterally, the flap is raised sufficiently to allow for possible eversion of the patella after the arthrotomy is performed.
  - An anterior medial parapatellar arthrotomy is then performed (TECH FIG 1C). The previous arthrotomy location is again preferred.
  - Care should be taken to preserve a cuff of tissue on the medial aspect of the patella to facilitate closure of the arthrotomy.
### COMPONENT EXPLANTATION

- Once the joint is opened, scar tissue is resected as necessary for adequate exposure. Specifically, the medial and lateral gutters should be restored with care to avoid injuring the collateral ligament origins. The suprapatellar pouch also should be restored via resection of scar tissue under the quadriceps tendon and from the anterior aspect of the distal femur just proximal to the femoral component.
- The subperiosteal flap is elevated off the proximal and anteromedial aspect of the tibia to allow exposure to the entire tibial component and proximal tibial bone.
- The tibial insert is removed from the tray to allow adequate visualization.
- The tibial tray is then explanted. In cases of a loose tibial component, intraoperative bone loss usually is minimal, and special techniques for tibial component removal are not required.
- In the septic knee with a well-fixed tibial component, bone-sparing techniques are used to remove the component.
- Stemmed tibial revision components are recommended when using augments to provide additional bony stabilization of the implant, thereby shifting some of the load from the damaged or deficient metaphyseal tibia to the diaphysis.

### MEDIAL OR LATERAL HEMIWEDGE AUGMENT

- The explanted proximal tibia is evaluated intraoperatively, and bone loss is compared to the preoperative radiographs. The appropriate preoperative plan is followed with anticipated changes verified by intraoperative findings.
- Intramedullary reaming is followed by placement of an intramedullary alignment guide, and a minimal transverse proximal tibial “skim” resection is taken after the tibial resection block is pinned in place (TECH FIG 2A,B).
- The appropriate wedge augment cutting guide is then selected and positioned over the previously placed cutting guide pins, and medial or lateral wedge cuts are performed (TECH FIG 2C).
- Once the proximal tibial surface is adequately prepared, a stemmed trial component that reflects the intramedullary stem to be used with attached augments is put in place (TECH FIG 2D).
- When adequate bony support is achieved, the joint surface is restored, and flexion and extension gaps are balanced, then the component to be implanted is constructed to match the trial and appropriately cemented into place (TECH FIG 2E).
- The goal is to place the tibial component directly onto a viable cortical rim of bone by converting noncontained defects into contained defects and to have a rigid press-fit intramedullary stem to support the tibial tray.
- This process applies to all of the wedge and block techniques.
Chapter 22  REVISION TKA WITH TIBIAL BONE LOSS: METAL AUGMENTS

TECHNIQUES

A. Intramedullary reaming should be carried to the depth of the stem available in the revision system in use.
B. The block is pinned into place after the guide is placed over the intramedullary reamer or trial stem extension, and a “clean up” or skim cut is made.
C. The pins from the previously used cutting block are maintained, the hemiwaedge block is slid over the pins, and the hemiwaedge cut is performed.
D. The trial tibial component is assembled and placed on the tibia, and if appropriate fit and stability are obtained, the final components are assembled.
E. The final component is cemented into place after tibial preparation is complete, and excess cement is removed after the assembled tibial component is impacted into place. (Courtesy of DePuy Orthopaedics, Inc., Warsaw, IN.)
FULL-WIDTH WEDGE AUGMENT

- Intramedullary reaming is followed by placement of an intramedullary alignment guide, and a minimal transverse proximal tibial “skim” resection is taken after the tibial resection guide is pinned in place.
- An appropriately angled full-width wedge augment cutting guide is then selected and positioned over the previously placed cutting guide pins, and the oblique full-width wedge cut is performed (TECH FIG 3).
- Once the proximal tibial surface is adequately prepared, a trial stemmed component that reflects the intramedullary stem to be utilized with the attached augment is trialed.
- When adequate bony support is achieved, the joint surface restored, and flexion and extension gaps balanced then the component to be implanted is constructed to match the trial and appropriately cemented into place.

TECH FIG 3 • Full-width wedge augment. Reaming is carried out as illustrated for the hemi-wedge technique, and a skim cut is performed if necessary. Then the full-width wedge block is pinned into place according to the technique for the system being used. The system in this illustration allows the block to be rotated, and an oblique skim cut can be made. Trialing and component assembly and insertion are carried out as in Tech Fig 2. (Courtesy of DePuy Orthopaedics, Inc., Warsaw, IN.)

MEDIAL OR LATERAL BLOCK OR STEP AUGMENT

- The explanted proximal tibia is evaluated intraoperatively, and bone loss is compared to the preoperative radiographs. The appropriate preoperative plan is followed, with anticipated changes verified by intraoperative findings.
- Intramedullary reaming is followed by placement of an intramedullary alignment guide, and a minimal transverse proximal tibial “skim” resection is taken after the tibial resection guide is pinned in place (TECH FIG 4A).
- The appropriate block augment cutting guide is then selected and positioned over the previously placed cutting guide pins, and medial or lateral step cuts are performed.
- Once the proximal tibial surface is adequately prepared, a trial stemmed component that reflects the intramedullary stem to be used with attached augment is trialed (TECH FIG 4B).
- When adequate bony support is achieved, the joint surface is restored and flexion and extension gaps balanced. The component to be implanted then is constructed to match the trial and appropriately cemented into place (TECH FIG 4C).

TECH FIG 4 • Medial or lateral block augmentation. A. Reaming and skim cutting are carried out as previously illustrated. Then the step cut is performed with the cutting block attached to either the intramedullary guide or a trial. B. The trial is assembled, and fit is evaluated. Additional freehand cleanup may be carried out to improve bone-to-component apposition in all of the illustrated techniques. C. The assembled revision component with attached block augment is cemented into the now-prepared tibia. (Courtesy of DePuy Orthopaedics, Inc., Warsaw, IN.)
Chapter 22 REVISION TKA WITH TIBIAL BONE LOSS: METAL AUGMENTS

**METAPHYSEAL CONE AUGMENTATION**

- The explanted proximal tibia is evaluated intraoperatively and bone loss is compared to the preoperative radiographs. The appropriate preoperative plan is followed, with anticipated changes verified by intraoperative findings.

- Intramedullary reaming should be carried to the depth of the stem available in the revision system in use (see Tech Fig 2A). Careful attention to tibial alignment while reaming is important. It may be necessary to ream slightly out of line with the tibial shaft to allow adequate space for the metaphyseal cone.

- Intramedullary reaming is followed by placement of an intramedullary alignment guide to evaluate for stem-to-tray mismatch. Some metaphyseal cone augmentation systems do not allow for offset stems.

- Once the appropriate-sized diaphyseal engaging stem is selected, the proximal tibia is sequentially broached with the appropriate-sized trial stem attached to the broach to provide proper alignment (TECH FIG 5A).

- The option for rotational disparity between the tibial tray and the cone is available in some systems. This allows the surgeon to rotate the broach if necessary to improve filling of a proximal metaphyseal defect.

- Broaching is carried out until rotational stability is obtained.

- Some systems then use the proximal surface of the broach as the cutting guide. This necessitates placing the broach at the level determined by preoperative planning and intraoperative assessment. Ideally, this position resects 2 mm or less of the proximal tibial metaphysis (TECH FIG 5B).

- Once the proximal tibia is resected and broached, a trial cone is placed and rotation is marked on the anterior tibia, a properly sized trial tibial tray and stem are assembled and placed through the cone, lack of excessive rotational disparity between the two is verified, and tibial tray rotation is marked (TECH FIG 5C).

- Both the tray with stem and the cone are removed, and the trial cone is assembled to the stemmed trial tibial tray. The assembled trial is placed back onto the proximal tibia, and trialing is completed as previously described.

- The selected trial is removed from the tibia and left assembled as a model for assembly of the final components.

- Final assembly of the tibial components is done to match the trial, and the tibial cone is impacted onto the Morse taper of the revision tibial base plate, with care taken to match the trial model cone rotation on the trial stem.

---

**TECH FIG 5** - Metaphyseal cone augmentation. **A.** After intramedullary reaming, a trial stem of the appropriate length is attached to the metaphyseal broach. Sequential broaching is carried out until good metaphyseal fill is obtained and the top of the broach is at the level of the planned skim cut. The handle is removed, and the broach is left in place. **B.** A skim cut is taken off the top of the broach. Careful attention should have been taken during broaching to ensure that the proximal surface of the broach rests at the planned level of the “clean up” cut. **C.** The trial tibial component is assembled and placed on the tibia. Careful attention should be given to tibial tray versus metaphyseal cone rotation. They may not be aligned with each other, depending on how the cone broach was rotated during broaching to gain maximal metaphyseal fill. The trial component assembly should be referenced during final component assembly. **D.** The final component is cemented into place after tibial preparation is complete. Care should be taken to keep the metaphyseal cone bone ingrowth surfaces free of cement during component insertion and impaction.
Cement is applied to the assembled component selectively, as most cones allow for bony ingrowth with a porous surface coating (TECH FIG 5D). If a diaphyseal press-fit stem is selected, cement is applied only to the proximal tibia and tibial base plate. Selection of a cemented-type metaphyseal stem may require step-cementing of the stem and tibial base plate, with no cement applied to the ongrowth surfaced metaphysical cone. This allows direct bony contact between the cone and the bone, allowing for ingrowth if cement is applied sparingly to the stem to prevent extrusion with tibial component impaction. If care is not taken, cement could potentially cover the cone and prevent bony ingrowth.

FREE TRABECULAR METAL AUGMENTATION

The explanted proximal tibia is evaluated intraoperatively, and bone loss is compared to the preoperative radiographs. The appropriate preoperative plan is followed, with anticipated changes verified by intraoperative findings.

Intramedullary reaming to obtain good diaphyseal fill is followed by placement of an intramedullary alignment guide to evaluate for stem-to-tray mismatch.

If coronal mismatch is found, consideration should be given to an offset stem.

Intramedullary reaming is followed by placement of an intramedullary alignment guide, and a minimal transverse proximal tibial “skim” resection is taken after the tibial resection guide is pinned in place.

The cavitory defect of the proximal tibia is curetted clean, and all membrane is removed.

The trabecular metal augment that most closely fits the defect is selected, and a high-speed burr is used to remove minimal amounts of bone to allow for a tight press-fit of the augment (TECH FIG 6A,B).

The augment is impacted into place. In cases in which the augment does not fully contact the surrounding bone, crushed cancellous allograft croutons can be combined with demineralized bone matrix to fill the peripheral void (TECH FIG 6C-E).

If an offset stem is selected to allow for good tibial coverage, or if the augment is placed off-center of the diaphysis to allow for best void fill, then a high-speed metal cutting burr can be used to trim the augment centrally.

Once clearance is obtained for the augment, the trial tibial stem with baseplate is inserted into the tibial diaphysis through the trabecular metal augment to verify fit.

When adequate bony support is achieved, the joint surface restored, and flexion and extension gaps balanced, the component to be implanted is constructed to match the trial and appropriately cemented into place.

The proximal portion of the tibial stem is cemented to the trabecular metal augment, and the stem is either press-fit in the tibial diaphysis or cemented per the preoperative plan (TECH FIG 6F).

TECH FIG 6 • Free trabecular metal augmentation. A. Trabecular metal augment sizing. The tibia is reamed as previously described, and a skim cut is taken off of the proximal tibia. The proximal metaphyseal defect is then sized by placing various-sized trials over the reamer on the tibial bone in an inverted position. B. Metaphyseal bone preparation. A tibial trial is constructed to determine the quantity and direction of any offset if required. A high-speed burr is then used to remove small amounts of bone, to allow full seating of the selected trabecular metal augment trial. Sufficient bone should have been removed to allow non-forceful seating of the trial, but full “fill” of the metaphyseal defect is not required. C. The trabecular metal augment trial and the tibial component trial are placed in the tibia simultaneously to verify lack of impingement between the two. If impingement is present, the augment may be either repositioned or directly trimmed with a burr to allow clearance of the tibial stem. (continued)
TECH FIG 6 • (continued) D,E. Once the trials have been inserted and appropriate fit has been achieved, the final augment is gently impacted into place. Excessive force may fracture the proximal tibia. Any defect that remains between the metaphyseal bone and the augment is one grafted to fill the void. Impaction grafting techniques may be used. F. Once the tibial augment is inserted and grafted, re-trialing of the tibial component is carried out. Additional removal of a small amount of the augment may be required to prevent impingement. The final component is impacted into the tibia with an adequate amount of cement to fill the void.

PEARLS AND PITFALLS

Block or wedge augment overhang  • An augment that overhangs the underlying tibial metaphyseal bone may irritate the medial collateral ligament or soft tissue envelope, particularly about the anterior and medial aspects of the knee. Downsizing of the tibial component or an offset stem may be required.

Joint line elevation  • Use of medial and lateral augments simultaneously should be an indication to carefully evaluate possible elevation of the joint line. If the joint line is restored, it may be preferable to use medial and lateral augments with a shorter insert to decrease the varus/valgus moment arm on the polyethylene.

Tibial stem to tibial tray mismatch  • The tibial tray that provides appropriate coverage of the proximal tibial with augmentation may not be centered over the tibial diaphysis. In this case, a central stem will move the tibial tray into an overhanging position or require downsizing that does not allow for adequate coverage of the proximal tibial. Offset stems are required to reconcile this mismatch.

Internal rotation of the tibial component  • Careful attention must be given to the rotational position of the cutting guide as it is pinned to the tibia. The second, or augment, cutting guide will be placed over the same pins as the first, or skim cut, guide was placed. Unlike some primary total knee techniques, rotation cannot be adjusted after the bone cut for the augment is made. All efforts should be made to verify appropriate rotation by anatomic landmarks, including the tibial tubercle and the insertion of the PCL.

Extensor mechanism/tibial tubercle  • In the face of significant bone loss in the proximal tibia, the extensor mechanism and its bony attachment should be handled with great care. Exposure of the knee should be accomplished without placing excessive tension on the patellar tendon. When step or slope cuts are made to accommodate wedges and block, careful attention should be paid to ensure preservation of bone about the tibial tubercle. Prevention of extensor mechanism disruption is of paramount importance.
POSTOPERATIVE CARE

- Postoperative care is directed by the intraoperative findings and the stability of the newly implanted component.
- If a proximally cemented stemmed component is seated on cortical bone with all defects contained after use of an augment, then immediate full weight bearing may be allowed.
- Range-of-motion exercises also may begin immediately if the skin over the anterior knee is in good condition postoperatively and the incision has been closed with no tension.
- In situations where the skin is under tension or the wound appears tenuous immediately postoperatively, then range-of-motion exercises are delayed, with the leg held in extension for the first 48 hours.
- The incision and skin are then reevaluated, and if there is no evidence of erythema or wound drainage, gradual range-of-motion exercises are started. The incision is watched carefully for drainage after range-of-motion exercises are initiated.
- When the tibial component is not fully supported directly by native metaphyseal bone, then toe-touch weight bearing should be initiated until incorporation of any allograft that was used in conjunction with augmentation.
- When bony ongrowth cones or free trabecular metal augmentation is used with less than full bony support, consideration should be given to delaying full weight bearing until bony ingrowth occurs.
- In cases in which partial weight bearing is initiated postoperatively, progression to full weight bearing can take place at 6 weeks postoperatively.
- As with primary TKA, deep vein thrombosis prophylaxis is mandatory and should follow usual protocols.
- We use 6 weeks of coumadin prophylaxis in the patient with no history of thrombosis or pulmonary embolism.
- We also use fractionated low-molecular-weight heparin starting 18 to 24 hours after the completion of surgery to protect the patient in the interval after surgery where the international normalized ratio has not yet reached our target of 1.8 to 2.2.

OUTCOMES

- Modular tibial augmentation systems were developed in the mid- to late-1980s and became broadly available by the early to mid-1990s; consequently, no long-term studies are available on the survivorship of this type of tibial component augmentation. A handful of midterm studies are available.
- In an early report on the use of tibial tray augmentation, Brand et al1 reported no failures in 22 knees with an average follow-up time of 37 months. The average age of the patients at the time of surgery was 70 years. There were no failures requiring revision and no loosening of the tibial component at the time of surgery. There were 79% excellent and 21% good results. There were no complications or reparations. Radiolucent lines beneath the metal wedge were present in 13 knees, but none were progressive.
- Haas et al11 used tibial augments combined with press-fit diaphyseal engaging stems to manage bone loss in revision TKA for aseptic failure. The average duration of follow-up was 3 years and 6 months (range, 2 to 9 years). Only patients who had had revision of the femoral component or the tibial component, or both, because of aseptic failure were included. The average preoperative Hospital for Special Surgery knee score was 49. Postoperatively, the knee score improved to an average of 76 points (range, 0 to 97 points). Eighty-four percent of patients had an excellent or good result.
- Hockman et al12 reported midterm results with one modular revision prosthesis. Fifty-four consecutive Coordinate (Deputy, Warsaw, IN) revision total knee arthroplasties were eligible for minimum 5-year follow-up. Nine knees failed and required either revision or component removal. Eight additional knees were considered clinical failures. Metallic augmentation was used in 89% of the knees, and large structural allografts were required in 48% of the knees. Revisions with bone loss that required bulk allograft failed less often (19.2%) than revisions managed without bulk allografts (42.9%). Modular augments did not effectively address the bone loss and instability encountered in many instances at revision surgery. Survivorship of the implant was 79% at 8 years in their study.
- Pagnano et al16 reported on early and midterm results using tibial wedge augmentation. Their mid-term report was a follow-up of their short-term study of 28 knees in 25 patients. The patients were originally reviewed 2.3 years after surgery, at which time 79% had excellent results and 21% had good results. Their midterm report was of 24 knees in 21 patients with metal wedge augmentation for tibial bone deficiency. The patients were reviewed 5.6 years clinically and 4.8 years radiographically after surgery. Clinical results were excellent in 67% and good in 29%. Radiolucent lines at the cement bone interface beneath the metal wedge were present in 13 knees. Eleven of the radiolucencies were <1 mm in width, and 2 were 1 to 3 mm in width. The authors stated that metal wedge augmentation for tibial bone deficiency is a useful option. No deterioration of the wedge-prosthesis or wedge-cement-bone interface was noted at midterm follow-up.
- Radnay and Scuderi18 reported a novel approach to tibial augmentation. They describe the use of free trabecular metal augments (see Techniquest). Ten tantalum tibial cones were press-fit into the prepared cavities with a series of revision TKAs. The stemmed tibial component was cemented into the implanted tibial cone and stems were press-fit in four knees and cemented in six knees. Offset stems were used in three tibias. At follow-up (average 10 months), radiographic evaluation revealed no evidence of loosening or change in position. Strength, range of motion, and stability were comparable to previously reported series of revision arthroplasties. The authors state that trabecular metal cones may eliminate the need for extensive bone grafting or structural allografts in revision knee arthroplasties.

COMPLICATIONS

- Complications of revision TKA with metallic tibial augmentation can be divided into two categories: early and delayed.
Perioperative or early complications can include intraoperative damage to neurovascular structures, extensor mechanism and collateral ligamentous disruption, and early postoperative infection.

Delayed complications most commonly include osteolysis, aseptic loosening, and late septic prosthetic arthropathy.

REFERENCES

DEFINITION
- During revision of the femoral component in total knee arthroplasty (TKA), bone loss from the distal femur is nearly inevitable.
- Deficient bone in the distal femur can be replaced by bone cement (polymethylmethacrylate), metal augments fixed to the revision femoral component, particulate bone graft or substitutes, bulk allograft to augment one or both femoral condyles, and complete replacement of the distal femur with allograft or metal.

ANATOMY
- The anatomy relevant to bone loss during revision total knee surgery consists of the metaphyseal femur, the medial and lateral epicondyles, and the medial and lateral femoral condyles.
- The femoral condyles represent the structural columns that support the revision femoral component. Accordingly, one goal of distal femoral reconstruction in revision TKA is to restore the condylar anatomy such that it can support a new component.

PATHOGENESIS
- The pathogenesis of distal femoral bone loss in revision TKA is related to removal of the previous implant and bone cement. Previous implants fixed to bone with cement or by porous ingrowth require dissection for mobilization and extraction; this process incurs a finite amount of bone loss.
- Even fine osteotomes and saws used to develop a plane between the implant and bone are space-occupying and cause bone loss from the distal femur. Aggressive extraction of well-fixed femoral components without first developing a plane between exposed metal and bone can result in avulsion of one or both femoral condyles.
- Correction of internal rotation of the previous femoral component will result in bone loss both anteriorly and posteriorly as the new component is oriented in the proper rotation.
- Osteopenia from stress-shielding of the periprosthetic femur, as well as osteolysis related to wear debris particles, can result in cavitary lesions in the distal femur that lead to significant bone loss.

NATURAL HISTORY
- Distal femoral bone loss, if severe, can result in the loss of structural integrity of the femur. When this occurs, the existing femoral component can migrate into varus or valgus relative to the femoral shaft.
- Surgical treatment is directed at augmenting this bone loss following removal of the previous loose, unstable femoral component.
- If left untreated, continued particulate debris and motion between loose components and bone can lead to continued symptoms and further bone loss in the distal femur of a failed TKA.

PATIENT HISTORY AND PHYSICAL FINDINGS
- The diagnosis of a failed TKA with loss of bone in the distal femur is best made by plain radiographs.
- The patient history is helpful in that findings in any of the following categories can alert the surgeon to the possibility that significant bone loss may be encountered during revision surgery: the time elapsed since the index arthroplasty; the type of implant and fixation used; any history of diseases such as osteoporosis; advanced age; corticosteroid use; use of cytotoxic drugs; irradiation; rheumatoid arthritis; and periprosthetic femoral fracture.
- Loose femoral components with associated bone loss will present with knee pain, swelling, and instability that is usually worsened by activity.
- Failed TKA femoral components with bone loss will have tenderness to palpation over the distal femur.
- An effusion may also be evident on physical examination.
- A grossly unstable component may result in ligamentous instability of the knee that is elicited on careful examination.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- High-quality radiographs of the knee can help in identifying and classifying a bone defect in the distal femur. The true lateral view of the knee joint can demonstrate the location and extent of osteolysis and bone loss in the distal femur. Oblique views of the knee often result in obscuring of bony detail by the metal implants. Therefore, a true lateral view of the knee should be obtained in 90 degrees of knee flexion, by placing the entire leg, including the knee and ankle joints, flat on the radiograph table.
- Other imaging modalities such as CT scans and metal-subtraction MRI scans may prove useful in defining the extent of bone loss in the distal femur, although the efficacy of these imaging studies in routine revision TKA is yet unproven.
- Intraoperative observation of bone loss after previous component removal and thorough débridement of osteolytic lesions and inflammatory membrane is the best determinant of the nature and extent of bone loss.
- The surgeon should be prepared for the worst-case scenario, because preoperative radiographs can underestimate the extent of bone loss adjacent to the existing femoral component.
- Accordingly, allograft bone, a wide range of revision implants, metal augments, and revision equipment should be available.
The diagnostic workup of femoral bone loss in revision TKA should include a thorough evaluation to exclude the possibility of knee sepsis.

- Preoperative nuclear medicine imaging, laboratory data, knee aspiration, and intraoperative frozen sections of periprosthetic tissues can assist in excluding sepsis.

**DIFFERENTIAL DIAGNOSIS**

- Deep knee sepsis can result in periprosthetic bone loss and is a relative contraindication to distal femoral reconstruction. Infection must be ruled out before reconstructing the distal femur in anticipation of implanting a revision femoral component.
- Stress-shielding of bone adjacent to the femoral component can result in bone loss from the distal femur. When the existing femoral component is extracted, severe loss of bone may be discovered in such cases.
- Osteopenia of the distal femur from osteoporosis, lytic lesions of bone such as benign bone cysts, neuropathic changes, and malignancy can also result in distal femoral bone loss, thereby complicating femoral reconstruction in TKA.

**NONOPERATIVE MANAGEMENT**

- Nonoperative management of severe distal femoral bone loss in a failed TKA should be reserved for debilitated patients in whom surgery is otherwise contraindicated.
- Severe medical comorbidities, integrity of the extensor mechanism, poor condition of the soft tissue, radiation necrosis of adjacent bone, immunosuppression, and metabolic bone disorders should be evaluated carefully to determine whether reconstruction of the distal femur is a reasonable option.
- Where major knee surgery is contraindicated, nonoperative measures such as analgesics, limited ambulation, assistive devices such as a walker or wheelchair, and knee bracing are alternative considerations.
- Chronic suppressive antibiotics may be an option in patients with bone loss from severe deep sepsis, in whom operative treatment is otherwise contraindicated.

**SURGICAL MANAGEMENT**

- Distal femoral bone loss can be managed surgically using bone cement, morselized bone graft, metal augments on the new prosthesis, bulk allograft reconstruction of noncontained defects of the medial or lateral condyles, and bulk allograft replacement of the distal femur with allograft or a special customized prosthesis.

**Preoperative Planning**

- Preoperative planning includes making sure the patient is medically optimized for major elective surgery, and excluding the possibility of deep sepsis in the knee. The surgeon should carefully assess existing scars, leg vascularity, nerve function, and the patient’s overall medical condition.
- Pre- and intraoperative assessment of collateral ligament integrity will help in choosing the appropriate implants.
- In grossly unstable knees, constrained implants or even rotating-hinge revision TKA implants may be indicated.
- If the surgeon prepares for the worst-case scenario, the correct equipment, implants, and personnel will be available to address any scenario. Practically, other than straightforward TKA revision cases with minimal femoral bone deficiency, the specialized resources needed to address severe distal femoral bone loss in TKA effectively limit such procedures to hospitals with the necessary equipment and expertise.
- A preoperative planning session with key personnel (ie, surgeon, assistants, implant representative) is invaluable in discussing the problem and considering all possible solutions. Efficient execution of the procedure requires planning and communication with the bone bank, implant representative, and operating room personnel.
- Structural allografts to rebuild deficient distal femoral condyles should include several allograft femoral heads.
- Fresh-frozen prepared specimens usually are favored because of their superior mechanical strength.
- Preoperative radiography and sizing of allograft tissue is desirable, but may not be practical or feasible.
- Instead, intraoperative preparation of the grafts with special equipment such as the Allogrip system (DePuy, Warsaw, IN) can shape the graft to proper dimensions so that wound closure is not a problem from an oversized graft.
- A full set of revision TKA instruments is essential, consisting of fine osteotomes to develop the plane between metal and bone, curettes, punches, reamers, Gigli saws, and instruments to clean out the intramedullary femoral canal.
- High-speed burrs attached to a pneumatic power driver can assist in loosening up well-fixed implants while preserving bone.
- A typical revision TKA instrument set from any major implant manufacturer has such instruments conveniently packaged in a single set.
- Porous tantalum metal augments are available for proximal tibia reconstruction in revision TKA, and soon may be available for distal femoral reconstruction as well. The advantage of this type of augments is that they heal rapidly to living host bone. These augments offer a custom reconstruction option that permits load-bearing and supports cement fixation.

**Positioning**

- The patient is placed supine, with a small pad under the ipsilateral buttock to ensure neutral position of the flexed knee. A Stulberg footrest or equivalent device is used to control knee flexion during surgery.
- The leg is scrubbed circumferentially and as far proximal as feasible to allow access to the thigh.
- In our practice, we do not use a tourniquet during any total knee procedure, but most surgeons exsanguinate the extremity with gravity or an Esmarch bandage before inflating a well-padded tourniquet applied to the proximal thigh.
- The surgeon must remain vigilant of the duration of tourniquet time, particularly if a long and complex reconstruction is anticipated.

**Approach**

- If several previous scars are present, the one chosen is the one closest to the midline that will allow extensile exposure proximally or distally. The most laterally based incision is the wisest as it preserves blood supply to the overlying skin. For most revision TKA surgery that involves distal femoral reconstruction, a standard medial parapatellar arthrotenomy will adequately expose the distal femur.
- Exposure can be facilitated by avoiding patella eversion in knee flexion. After the patella component is addressed in knee flexion, a medial parapatellar approach is used.
extension, the patella can be pushed into the lateral gutter and retracted safely.

- In our experience, exposure of the distal femur is improved if patella eversion is avoided.
- To understand the extent of bone loss, inflammatory membranous tissue overlying the femoral bone after removal of the previous component must be dissected away. The electrocautery knife works well for this purpose. Previous membrane and granulomas must be débrided thoroughly to appreciate the amount of distal femur available for reconstruction.
- Anteriorly, a proximal quadricepsplasty,\textsuperscript{3,9} tibial tubercle osteotomy,\textsuperscript{2} or other specialized dissection may be needed to mobilize the extensor mechanism safely, and expose the distal femoral cortex.
- The exposure chosen depends on the difficulty in exposing the distal femur and the extent of débridement and preparation for bone reconstruction required.

---

**MORSELIZED ALLOGRAFT OR BONE CEMENT**

- Small, contained defects in the femoral condyles can be filled with bone cement or morselized autograft or allograft.\textsuperscript{10} These grafts are not load-bearing and are suitable only for focal, cystic lesions that are surrounded by intact, structural bone (**TECH FIG 1**).
  - A burr or curette is effective in cleaning out in preparing such defects.
  - Optimize allograft–host bone contact by excising the inflammatory membrane, removing previous metal and cement particles, and creating a viable and healthy host bone bed.
  - Morselize an allograft femoral head using small acetabular reamers. Pack graft into the defects, and cement the revision implant in place.
  - Alternatively, bone cement or a synthetic bone graft substitute filler can be used to pack small, contained defects between the revision implant and host bone.

**TECH FIG 1** - Cavitary, contained defects that do not affect the structural integrity of the distal femur can be packed with cement, morselized autograft or allograft, or synthetic bone fillers.

---

**METAL AUGMENTS ON REVISION FEMORAL COMPONENT**

- After excision of previous cement and inflammatory granulomas, remove the minimum amount of bone from the distal and posterior femoral condyles to expose viable host bone (**TECH FIG 2A,C**).
  - Small defects in the distal and posterior femoral condyles can be reconstructed by using metal augments on the revision femoral component\textsuperscript{8} (**TECH FIG 2B,D**).
  - Determine the joint line by examining the position of the epicondyles, the existing femoral component, position of the patella relative to the femur, contralateral knee radiographs, and the contour of the posterior femoral condyles projected laterally.
  - A combination of these variables makes it possible to estimate the joint line accurately and recreate it.
  - Removal of additional bone from the distal femur will move the joint line more proximally.
  - Impact the trial femoral component on the distal femur, and measure the defects between metal and host bone distally, anteriorly, and posteriorly after determining proper external rotation of the component.
  - Reinsert the trial implant after installing trial augments of the appropriate thickness and check the fit.
  - Augments in revision TKA systems come in a variety of thicknesses to accommodate femoral bone loss from the anterior cortex, posterior condyles, and distal femoral condyles.
  - The goal of revision component augmentation is stable contact between metal and host bone without resorting to a custom implant.
  - If metal augments are used on the revision femoral component, an intramedullary rod extension should be attached to the revision femoral component to achieve initial implant stability.\textsuperscript{8}
TECH FIG 3 • A, B. Severe and complete loss of structural bone in the condyle of the distal femur can be addressed with bulk femoral head allograft to rebuild the deficient bone. C. Acetabular reamers are used to prepare the host condyle for a matching allograft. (continued)

BULK FEMORAL HEAD RECONSTRUCTION OF CONDYLAR DEFECTS

- If one or both femoral condyles are not amenable to reconstruction with metal augments, structural deficiencies can be addressed with allograft tissue (TECH FIG 3A, B).
- The condylar defect is reamed with small-diameter male acetabular reamers from the Allogrip system (DePuy, Warsaw, IN; TECH FIG 3C).
- Matched-diameter female reamers are used to prepare the convex surface of the allograft femoral head (TECH FIG 3D).
- The allograft femoral head is then placed in the reamed defect. Either a whole or a half femoral head allograft will fill the cavitary defect, where it is attached to host bone with cancellous screws (TECH FIG 3E).

- Then, the allograft-host bone composite is cut to match the size of the revision femoral component.
- Metal augments may be needed for residual bone defects remaining after femoral head allograft reconstruction of the femoral condyles, or to recreate the joint line.
- The technique of using metal augments on the revision femoral component is described above.
- Attention must be maintained throughout to ensure recreation of the joint line and of the appropriate external rotation of the femoral component needed for patella stability.

TECH FIG 2 • Bone loss that affects a limited part of the distal femoral condyle can be addressed with metal augments attached to the revision femoral component. Reconstruction of the femur shown in A will require a posterior metal augment (B); that shown in C will need both posterior and distal metal augments (D).
D. The Allogrip system is illustrated, with a femoral head allograft held tightly in the vise while female acetabular reamers expose cancellous bone and size the graft to match the condylar defect. E. The cavitory defect in the femur is filled with a bisected femoral head allograft, which is flush against host bone and stabilized with two compression screws.

TECH FIG 3 • (continued) D. The Allogrip system is illustrated, with a femoral head allograft held tightly in the vise while female acetabular reamers expose cancellous bone and size the graft to match the condylar defect. E. The cavitory defect in the femur is filled with a bisected femoral head allograft, which is flush against host bone and stabilized with two compression screws.

BULK ALLOGRAFT REPLACEMENT OF THE DISTAL FEMUR

- For extensive loss of the distal femur, reconstruction with bulk allograft replacement of deficient bone is a proven option.¹
- If extensive bone loss leaves only an intact cortical shell in the distal femur, an undersized distal femur bulk allograft matched to the operative side can be stabilized within the host cortical shell (TECH FIG 4A).
- The proximal end of the graft should rest against viable host bone, with mechanical stability and maximum host bone–allograft contact to promote healing.
- Conservative resection of the distal femur to match the end of the allograft will accomplish contact between host bone and allograft.
- Once stabilized, the allograft distal femur within the host cortex is sized and cut to match the revision femoral component.

TECH FIG 4 • A. Severe deficiency of both femoral condyles can be addressed by pressing an undersized distal femoral allograft into this void, while retaining the host cortical bone around it. After stabilization to surrounding host bone with screws, the allograft–host composite is shaped to receive the revision femoral component. B. To replace the distal femur, existing epicondyles are osteotomized, and the deficient distal femur is cut to expose viable, stable host bone. In this case, a bulk distal femoral allograft will be used to rebuild the femur. C. The allograft femur is in place, with host epicondyles and distal femur shown. (continued)
Chapter 23  REVISION TKA WITH FEMORAL BONE LOSS: DISTAL FEMORAL REPLACEMENT 967

TECHNIQUES

PEARLS AND PITFALLS

Preparations
- Preparation is the key, with a team conference to review radiographs and assess the availability of equipment, resources, and personnel required for the femoral reconstruction. Anticipate more bone loss than that seen on radiographs and prepare for the worst-case scenario.

Implants
- Have a wide selection of implants available, with metal augments, intramedullary rod extensions, offsets, and implants with increasing amounts of constraint.

Grafts
- Several allograft femoral heads and equipment for milling, grinding, and shaping these heads should be available. Fixation of grafts to host bone requires interfragmentary screws and small plates, which should be readily available. Two or more graft specimens must be available for distal femoral allograft replacement so that the closest size can be chosen.

- After implantation of the revision component (TECH FIG 4D), the epicondyles should be attached to the allograft with cancellous screws augmented with washers. To accomplish this step, the epicondyles on the bulk allograft must be cut off and removed.

- Before final implantation, check the soft tissue envelope to make sure inadvertent over-sizing has not occurred.

TECH FIG 4 • (continued) D. The revision implant is positioned in the bulk allograft that was cut to accept the implant. An intramedullary rod provides additional fixation in the distal host femur. The medial and lateral epicondyles have been screwed into their corresponding anatomic locations on the bulk allograft.

REPLACEMENT OF DISTAL FEMUR WITH A TUMOR RECONSTRUCTION PROSTHESIS

- For severe loss of the metaphyseal and diaphyseal femur (such as in tumor resection), modular implants designed for limb salvage may be the only option for reconstruction.5
  - This option is reserved for cases in which the extent of bone loss precludes reconstruction with bulk allograft.
  - Template radiographs and have appropriate reconstruction systems available, with varying modular lengths to rebuild the deficient femur.
  - Perform an osteotomy of the femur to expose viable bone that is suitable for weight bearing.
  - Prepare the femur retrograde for cementing, using techniques similar to those for cementing a femoral implant in total hip replacement surgery.
  - Use trial and error to reproduce the appropriate limb length, soft tissue tension, and implant rotation. This is most easily accomplished by reconstructing the tibial side first, so that all trial reductions can be assessed by changing the femoral side only, thereby simplifying the procedure.

- When correct rotation and length are determined, mark the host bone and implant to reproduce this rotation, and cement the implant into the distal femur to the appropriate depth, and in the desired rotation.
  - Uncemented fixation into the distal femur may be an option with some reconstruction systems.
  - Assemble the knee articulation (these designs usually rely on a rotating hinge articulation with multidirectional constraint built into the articulation).

  - In severe cases, or if the proximal femur is unsuitable for mechanical fixation with an intramedullary rod, the entire femur can be bypassed with metal.
  - In such cases of complete femoral replacement, a rotating hinge knee reconstruction is done at the distal end, and a constrained hip replacement at the proximal end.
Graft sizing can be judged by preoperative radiographs of the graft superimposed on the patient’s knee, or by intraoperative assessment. Oversized grafts will present problems with wound closure; check soft tissue tension before final fixation of the graft to host bone.

Experience and resources
Be realistic about surgeon experience, support, equipment, and resources available to perform complex distal femoral reconstruction. Specialized training and intense equipment and personnel demands effectively preclude smaller community institutions from doing such surgery.

Operative time
Either avoid using a tourniquet, or be wary of the tourniquet time in lengthy total knee reconstructions. If necessary, the tourniquet can be let down for selected parts of the procedure to minimize limb ischemia time.

POSTOPERATIVE CARE
The goal of distal femoral reconstruction is to achieve initial mechanical stability. Accordingly, the surgeon should aim for weight bearing as soon as possible after surgery.

If allograft reconstruction of the femur is necessary, healing to host bone occurs over a prolonged time. Therefore, protected weight bearing will be required for an extended period of time in such cases.

Assistive devices such as a cane, walker, or crutches should be prescribed in all revision TKA with distal femoral reconstruction to protect the patient against accidental falls or twists on the reconstructed knee, and to allow healing of graft tissue.

Range of motion should be assessed intraoperatively following distal femur reconstruction. Usually, the range of motion will depend on the quality of the soft tissues and integrity of the extensor mechanism, assuming mechanical stability of the reconstruction has been achieved. If knee range of movement must be limited for a period of time, a knee brace that allows movement only through a prescribed arc of motion may be necessary.

Straight leg raises, isometric exercises, and ankle and calf rehabilitation should be possible soon after all distal femoral reconstructions.

A multimodal deep venous thrombosis prevention regimen should be instituted after surgery, and the patient monitored as appropriate.

OUTCOMES
Radiographs at regular intervals and patient interviews will allow assessment of outcomes. Radiographs should be assessed for stability of the reconstruction, and for healing of bone at the allograft–host bone junction.

Bulk allografts heal to living host bone, and allograft bone away from this healed junction remains non-viable over the long term. In load-sharing configurations, where the allograft is supported by host bone or by metal implants, the long-term outcomes are excellent.

If allograft bone is used in load-bearing configurations, late failure of the non-viable bone from repetitive loading is predictable.

Allograft bone cannot remodel in response to stress; therefore, intramedullary stems that bypass the graft completely and transfer loads to living host bone are essential during the reconstruction.

In some complex reconstructions involving distal femur replacements with bulk allograft or limb salvage implants, the patient should be counseled to use protected weight bearing for a prolonged time, such as 6 months or longer.

COMPLICATIONS
A postoperative infection is a devastating complication following complex distal femoral reconstruction with allograft bone. Early diagnosis and aggressive wound débridement may salvage the situation in some instances, but removal of all allograft, cement, and implants in preparation for a staged reconstruction usually is necessary.

Late deep infections with a virulent organism in a knee with massive bone loss and allograft reconstruction of deficient host bone may necessitate a limb amputation.

Mechanical failure of distal femoral reconstructions usually occurs if the surgeon fails to achieve initial mechanical stability. Repeat surgery is necessary to rebuild the femur and achieve rotational and axial stability to permit protected weight bearing after the procedure.

Because anticoagulation for prophylaxis against deep venous thrombosis is necessary after distal femoral reconstruction in revision TKA, the surgeon should monitor the patient for a postoperative bleed.

If a tense hematoma develops, or new wound drainage is encountered, aggressive surgical debridement should be considered early, to avoid the risk of infection.

REFERENCES
DEFINITION
- Substantial bone loss and bone defects are among the most challenging problems faced by surgeons performing revision knee arthroplasty. Tibial bone loss in failed total knee arthroplasty (TKA) is a complex and difficult problem.
- Awareness and proper management of bone loss, through cement fill, metal augments, or bone grafting, are crucial for achieving stability and longevity of the newly implanted revision components.

ANATOMY
- Tibial bone loss during revision TKA is common. The most common areas of deficiency involve the posterolateral and medial tibial plateau.
- Smaller contained defects can often be addressed with morselized bone graft or cement alone. Larger, uncontained defects may require the use of metallic wedges or structural allografts.

PATHOGENESIS
- The etiology of bone loss after TKA is multifactorial. Bone stock deficiency may result from any of the following causes:
  - Stress shielding of the proximal tibia and distal femur can cause clinically significant osteopenia surrounding the knee following TKA.
  - Osteolysis is a biologic response to wear debris following TKA that can result in bony destruction.
  - Aseptic implant loosening can result in pathologic micromotion at the implant–bone interface, resulting in increased wear debris and formation of a biologically active membrane.
  - Removal of well-fixed implants, even using proper technique, can result in some degree of bone loss, particularly from the subchondral region.

NATURAL HISTORY
- Regardless of the mechanism of bone loss, once significant bony destruction is visible on plain radiographs, it is likely that continuing progression leading to failure of the knee arthroplasty will occur.
- In this spiral toward implant failure, patients may be asymptomatic initially, but pain, swelling, and instability, including hyperextension due to loss of tibial height, can be expected and are likely sequelae of the failing TKA with significant tibial bone loss.

PATIENT HISTORY AND PHYSICAL FINDINGS
- Patient history and physical findings can range from completely asymptomatic to debilitating pain and instability with normal gait walking.
  - A full history and physical examination are essential, and should include an assessment of type, quality, location, and duration of pain. Any new, severe pain or progressive pain in a previously well-functioning implant, particularly during weight bearing, is of particular concern. The presence of start up pain is also important to elicit in the history.
  - Additional questions should focus on the stability of the knee. A new onset of slowly progressive symptoms “giving out” or weakness of the knee can be an indication of problems.
  - Local tenderness along the interface between the tibial implant and the tibia can be seen in tibial component loosening. This should be distinguished from local tenderness over the pes anserine bursa.
  - Finally, as with all patients undergoing revision knee replacement, infection must be ruled out.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- A thorough clinical and radiographic evaluation is a prerequisite for revision TKA. The extent and location of bone loss, the quality of the remaining bone, the degree of cortical continuity, and the absence of infection must be determined.
- Standing anteroposterior, lateral, and patellar radiographs usually are sufficient for assessment of tibial bone loss, but CT scans can be more accurate in estimating the degree of bone loss and may be helpful when there is massive bone loss or abnormal anatomy.
- All patients should have the appropriate infection laboratory studies (ie, complete blood count, C-reactive protein, erythrocyte sedimentation rate) as well as an attempt at knee aspiration and synovial fluid sent for Gram stain, cell count, and culture. Serial knee aspirations with repeat laboratory studies often are performed on patients with a high index of suspicion for infection.

DIFFERENTIAL DIAGNOSIS
- Bone loss in TKA may result from the following factors, singly or in combination:
  - Stress shielding
  - Osteolysis
  - Instability
  - Implant failure (malalignment)
  - Infection (must be evaluated and ruled out before reconstruction begins).
- In addition, extremity pain in a patient with a TKA can have several possible nonsurgical diagnoses, including:
  - Referred pain from hip, thigh, or calf
  - Complex regional pain syndrome
  - Pes anserine bursitis
  - Patellar or hamstring tendinitis
  - Crystalline deposition disease (ie, gout or pseudogout)
  - Neurovascular problems: neuropathy, radiculopathy, spinal stenosis
- Tumor (needs to be considered)
- Vascular claudication
- Thrombophlebitis or deep vein thrombosis
- Fibromyalgia

**NONOPERATIVE MANAGEMENT**

- Nonoperative management of a painful TKA with tibial bone loss is not often indicated. However, if revision is not deemed a safe option for medical, psychosocial, or other reasons, management is similar to that for a patient with end-stage knee arthritis.
- Treatment options are symptom based and can include activity modification, walking aids, nonsteroidal pain medications, and bracing.

**SURGICAL MANAGEMENT**

- Various joint reconstruction techniques have been described for dealing with bone loss. The choice of reconstruction depends largely on the type of bone loss (ie, contained or uncontained) and the location and size of the defect (Table 1).

<table>

</tr>
</tbody>
</table>

**Preoperative Planning**

- Bone loss around a knee implant should be assessed systematically, including both femoral condyles, both tibial plateaus, and the patellofemoral joint.
- Location of the joint line is marked. Reference points include the fibular head and the epicondyles of the femur. The joint line typically sits 20 to 25 mm distal to the lateral epicondyle.
- The magnitude of bone loss has significant implications for decisions regarding the use of bone graft or prosthesis augmentation, choice of prosthesis sizing, selection of articular constraint, and need for supplemental stem fixation.

**Positioning**

- Revision TKA usually is performed with the patient in the supine position.

**Approach**

- A standard medial parapatellar approach to the knee is used. The medial collateral ligament is circumferentially released from the proximal tibial metaphysis as a single sleeve.
- Additional exposure often is required if metal wire mesh is used for uncontained defects. The proximal portion of the tibia must be well exposed to ensure fixation of the wire mesh onto the bone. External rotation of the tibia and elevation of the medial sleeve often help with exposure of the cortical margins.
- The patellar tendon should be protected throughout the entire procedure, and the patella should not be everted, to minimize the risk of avulsion. In cases with severe joint ankylosis, the surgeon should be prepared to convert to more extensive revision approaches if necessary to obtain visualization (eg, quadriceps snip, tibial tubercle osteotomy, or V-Y quadricepsplasty).
Chapter 24  REVISION TKA WITH TIBIAL BONE LOSS: BONE GRAFTING

**IMPACTION GRAFTING**

- Full exposure of the knee joint is accomplished using a standard medial parapatellar arthrotomy, as described earlier.
- A formal synovectomy with sharp dissection is performed for removal of polyethylene wear particles and improved exposure.
- Following removal of the components, a high-speed burr is used to define bony lesions, clean multiloculated defects from cavitary defects, and decorticate sclerotic areas.

**Contained Defects**

- Contained defects require impaction of bone directly into the defect (TECH FIG 1).
- Cancellous allograft is introduced into the tibial canal.
- A trial stem is inserted into the tibial canal in proper alignment, bone graft is impacted around the stem, and the stem is removed when the bone graft has filled the defect.

**Uncontained Defects**

- Uncontained defects call for wire mesh to reproduce the cortical anatomy (TECH FIG 2).
- Wire mesh is molded to estimate normal contours of the proximal tibia and is held in place with small cortical screws.
- A central intramedullary guide rod with cement restrictor is inserted to allow a gap of 2 cm from the anticipated end of the final tibial stem component.
- A trial tibial stem is inserted into the tibial canal in neutral alignment. The final chosen stem should be smaller to allow for a 2-mm circumferential cement mantle.
- Thawed fresh-frozen morselized cancellous allograft is introduced into the tibial canal and impacted tightly around the stem using either cannulated or standard tamps and a mallet.
- The trial stem is removed, leaving a restored mantle of cancellous bone.
- The stemmed tibial prosthesis is cemented in standard fashion.

**TECH FIG 1**  Contained tibial defect in the same patient shown in Figure 1A,B.  A. Primary components have been removed, and the lesion has been found to have intact cortices.  B. Cancellous allograft is introduced into the tibial canal.  C,D. A trial stem is inserted into the tibial canal in proper alignment, bone graft is impacted around the stem, and when the bone graft has filled the defect, the stem is removed.  E,F. Postoperative AP and lateral radiographs after completion of the tibial impaction grafting and cementing of the final components.
TECH FIG 2 • Uncontained tibial defect in the same patient shown in Figure 1C. A. Intraoperative photograph showing a wire mesh cage contoured to reestablish approximate proximal tibial anatomy and held in place with small cortical screws. B. The trial tibial stem is inserted in proper alignment, and bone graft is impacted surrounding the stem. (The trial used is larger than the actual stem to allow for several millimeters of cement mantle.) C. The trial tibial stem is removed. D,E. Cement is introduced in the impaction grafting site, the real component is inserted, and excess cement is removed. F. Intraoperative photograph showing the final components. G,H. Postoperative AP and lateral radiographs show reconstruction of the tibial plateau with wire mesh and impaction grafting.

STRATEGIC FEMORAL HEAD ALLOGRAFT

- Preoperatively, estimate the size of the defect and order appropriate-sized femoral head allografts.
- Thaw the allograft material in warm saline for 15 to 20 minutes and mount in a grip device.
- Preparation of the allograft requires the use of a male and female acetabular reamer system (DePuy, Warsaw, IN).
  - Female-type acetabular reamers are used to remove retained cartilage and bone (TECH FIG 3A).
  - Flush the structural allograft with saline to remove marrow elements.
  - The tibial defect is denuded of all nonviable tissue.
  - If sclerotic bone is encountered, the reamer may wander. In these cases, a high-speed burr may be used to remove sclerotic bone.
- A male-type reamer no larger than prepared allograft is used to prepare host bone (TECH FIG 3B). The host bone is reamed to expose healthy, bleeding cancellous bone, including removal of all fibrous tissue and cement.
- The allograft is placed into the defect and provisionally secured with K-wires or Steinmann pins. These should be placed so that they do not interfere with the stemmed prosthesis insertion (TECH FIG 3C,D).
- Revision cutting guides are used to trim allograft for component implantation. Tibial component preparation should follow standard revision principles.
- The K-wires are replaced with partially threaded 4.0- or 4.5-mm cancellous screws, and the tibial component is press-fit or cemented in the standard fashion (TECH FIG 3E-G).
### TECH FIG 3  •  Femoral head allografting.

A. The femoral head allograft is secured into a grip device and a female-type cheese grate reamer is used to denude the allograft of cartilage and subchondral bone. B. A male-type reamer of appropriate size is used to create a socket for the allograft. C,D. The allograft is impacted into place and secured with K-wires. E. The allograft is cut to the appropriate height and fixed with cancellous bone screws. F,G. Final AP and lateral radiographs of the medial tibial plateau reconstruction with femoral head allograft secured with screw fixation. (From Hanssen A. Managing severe bone loss in revision knee arthroplasty. In: Lotke PA, Lonner JH, eds. Knee Arthroplasty, 2nd ed. Philadelphia: Lippincott Williams & Wilkins, 2003:321–344.)

POSTOPERATIVE CARE

- Unless a tibial tubercle osteotomy is performed, standard postoperative care, including use of continuous passive motion machine, weight bearing as tolerated, and status with physical therapy is indicated.
- However, the priority should be wound healing and incorporation of the graft. Therefore, the aggressiveness of the postoperative course depends on the type of reconstruction and the security of component or graft fixation.

OUTCOMES

- Lotke et al.\(^2\) recently reported prospectively on 48 consecutive patients treated with impaction allograft for substantial bone loss in revision TKA. They found no mechanical failures, and all radiographs showed incorporation and remodeling of the bone graft. They also found an improvement in Knee Society score from 52.3 to 80.3. Six complications (14%) were reported, including two infections and two periprosthetic fractures.

COMPLICATIONS

- Bone graft resorption
- Graft collapse
- Infection
- Patellar clunk
- Instability
- Joint line elevation
- Stiffness
- Periprosthetic fracture

REFERENCES

DEFINITION

- Estimates indicate that by the year 2030 the volume of primary total knee arthroplasty cases will have increased to 3,480,000, and the number of revision procedures is expected to rise accordingly, to 268,200.¹
- Indications for removing well-fixed total knee components include infection, malalignment, malpositioning, instability, periprosthetic fracture, stiffness, or aseptic loosening of the other part(s).
- Achieving the goal of safe removal of well-fixed components during revision total knee arthroplasty (TKA) depends on meticulous surgical technique and availability of the appropriate instruments. In many ways, these are the most important portions of the revision TKA procedure, because careless technique may lead to damage of the remaining bone stock, iatrogenic fracture, and disruption of soft tissues, ultimately compromising the quality of the revision construct and the outcome for the patient.

ANATOMY

- Removal of well-fixed TKA components necessitates adequate exposure.
- Proper management of the extensor mechanism is essential. A medial parapatellar arthrotomy may not provide the exposure required for component removal and subsequent reconstruction. Extensile exposure techniques using a tibial tubercle osteotomy, quadriceps snip, or V-Y quadricepsplasty, are described in Chapters AR-26 and AR-27.

PATHOGENESIS

- Indications for removal of well-fixed TKA components include infection, malalignment, malpositioning, instability, periprosthetic fracture, stiffness, or aseptic loosening of the other component(s).

PATIENT HISTORY AND PHYSICAL FINDINGS

- The history and physical examination should be directed to determine whether the patient’s pain is extrinsic or intrinsic to the TKA.
- Extrinsic sources of pain (eg, lumbar radiculopathy, referred hip pain) should be considered in the differential diagnosis.
- Pain that is determined to be intrinsic to the TKA should be correlated with the history, physical examination, and radiographic findings to confirm that the cause of the pain can be corrected with revision TKA.
- Failure to identify a cause for the patient’s pain before performing the revision TKA portends a poor prognosis.
- Physical examination includes the following:
  - Visual inspection of the previous incision and the surrounding skin. The most appropriate, lateral-most incision is selected to avoid wound necrosis and maximize healing potential.
  - Passive and active range of motion (ROM) are assessed. ROM postoperatively predominantly depends on their preoperative ROM. Normal ROM after TKA ranges from full extension to 120 to 135 degrees. It is important to inform patients that revision TKA may not improve their ROM. Stiff knees may require extensile exposure techniques or capsular releases. Extensor lag may indicate a deficient extensor mechanism.
  - The medial and lateral collateral ligaments are tested in full extension and at 30 degrees of flexion. Coronal plane instability may make it necessary to remove well-fixed components and implant components with more constraint.
  - The anterior and posterior stability of the knee is assessed. Sagittal plane instability may make it necessary to remove components to improve flexion-extension gap balancing or to compensate for a deficient posterior cruciate ligament in patients with a cruciate-retaining design.
  - The coronal plane alignment is assessed with the patient standing. The femorotibial angle is measured; it usually is 5 to 7 degrees of valgus. It may be necessary to remove well-fixed components to correct malalignment.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Standing anteroposterior (AP), lateral, and patellofemoral radiographic views are essential.
- Full-length standing AP radiographs are useful to determine the overall mechanical alignment of the lower limb.
- The radiographs must show the diaphysis well above the femoral prosthesis and well below the tibial prosthesis.
- The radiographs are assessed for alignment, component positioning and size, joint line position, loosening, and bone stock and osteolysis.
- CT scans may be useful to assess for osteolytic lesions or to assess for femoral and tibial component rotation.
- Inflammatory markers, erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP), are obtained to screen for the presence of infection.
- Aspiration of the knee is indicated if either the ESR or CRP is elevated or if there is clinical suspicion of infection.

DIFFERENTIAL DIAGNOSIS

- Lumbar radiculopathy
- Hip pathology
- Neuropathy
- Complex regional pain syndrome
- Vascular claudication
- Primary bone tumors
- Metastatic disease
- Trauma

NONOPERATIVE MANAGEMENT

- Nonoperative management of the failed TKA may consist of activity modification, physical therapy, bracing, and consultation with pain management specialists.
SURGICAL MANAGEMENT
- Surgical management begins with preoperative planning.
- The patient’s history, physical examination, radiographs, and laboratory studies are reviewed well in advance of the surgery, to allow for adequate preparation time.
- The cause for failure of the TKA is determined.
- The surgical plan is delineated, with a primary plan formulated and contingency plans developed.
- The appropriate instrumentation, implants, and bone graft (if necessary) are ordered.
- The knee is exposed, with extensile approaches if necessary.
- The components are removed carefully, with meticulous attention paid to preservation of bone stock and the soft tissues.
- The knee is subsequently reconstructed.
- Layered closure is performed carefully.

Preoperative Planning
- The key to any successful revision TKA is preoperative planning. The reason for failure of the original TKA is determined from study of the preoperative history, physical examination, imaging studies, and laboratory results.
- It is decided whether removal of all femoral, tibial, and patella components is necessary or if an individual component can be left in situ.
- The previous operative reports are reviewed, with particular attention paid to the surgical approach, releases performed, and implants that were used.
- The operative report or implant stickers should be reviewed carefully. One should determine whether the tibial polyethylene component is modular and what sterilization method was used for it. If some of the index TKA components are to remain in situ, the surgeon must determine whether compatible parts are available.
- Radiographs are reviewed for bone stock quality and quantity.
- Particular attention is paid to the fixation method of the components. Stems that were cemented may require the use of ultrasonic tools for removal of the remaining cement.

Positioning
- The patient is positioned supine on the operating room table.
- A bump is placed so that the foot can be supported with the knee in flexion (FIG 1).
- The knee is draped to allow for an extensile surgical exposure.

Approach
- The preferred surgical approach is a standard medial parapatellar approach, although an extensile approach may be necessary (see Chaps. AR-27 and AR-28).
- Adequate exposure of the components to ease implant removal and subsequent reconstruction is crucial.
- A variety of instruments can be used to remove the well-fixed TKA implant: osteotomes, Gigli saws, punches, saws, burrs, metal-cutting discs or burrs, and ultrasonic tools.
- Implant removal proceeds in the following order (if all components are being removed): tibial polyethylene, tibial tray, femoral component, patella component.
- We prefer to remove the tibial tray before we remove the femoral component to protect the femoral bone from the retractors. However, if it is difficult to remove the tibial tray with the femoral component still in place, it may be necessary to remove the femoral component first. If this is the case, the femoral bone can be protected with sponges.

EXPOSURE
- The extensor mechanism must be subluxated laterally, with careful attention to avoid detaching the insertion of the patella tendon.
- A thorough synovectomy is performed, and the medial and lateral gutters are recreated.
- The collateral ligaments must be identified and protected.
- The interface of the femoral, tibial, and patellar components with bone must be visualized.

TIBIAL COMPONENT POLYETHYLENE REMOVAL
- The tibial polyethylene is removed first to increase the space within which the surgeon can work to remove the components.
- If a modular implant was used, it is removed by inserting an osteotome at the interface of the polyethylene and the tray and levering the polyethylene out. This can even be accomplished with a nonmodular design (TECH FIG 1).
- Certain posterior-stabilized designs have a reinforcing metal pin in the post that may need to be removed before the insert can be levered out. A saw can be used to divide the post, and the pin can be removed with a rongeur.
- Some inserts also are secured to the tray with a clip or screws. Therefore, it may be necessary to order special instruments from the implant manufacturer to facilitate removal.
Chapter 25  REVISION TKA WITH REMOVAL OF WELL-FIXED COMPONENTS

**TIBIAL COMPONENT REMOVAL**

- The prosthesis–cement interface is targeted in cemented components.
- The prosthesis–bone interface is targeted in uncemented components.
- The target interface is disrupted with a thin sawblade, with careful protection of the soft tissues (TECH FIG 2A).
- The area under the tray that is not accessible to the saw is disrupted with osteotomes (TECH FIG 2B). The tibia can be externally rotated to provide access to the posterior aspect of the component. Care must be taken to protect the neurovascular structures posteriorly.
- A clear path for egress of the tibial component must be achieved. The posterolateral aspect of the tibial component must clear the posterolateral femoral condyle. To achieve this, hyperflexion and anterior dislocation of the knee is necessary. Care must be taken to avoid avulsion of the patella tendon.
- It may be necessary to remove the femoral component first if it blocks a clear trajectory for tibial component removal.
- The tray can be gently disimpacted with a punch (TECH FIG 2C). If the component does not separate readily from the cement mantle–bone portion, then further work with the osteotomes is necessary. Excessive force will lead to unnecessary bone loss or fracture.
- The implant can be separated from the cement or bone by stacking broad osteotomes. One should avoid trying to lever the implant out with the osteotomes, because this may lead to fracture. Once the implant is separated from the cement or bone, it can be removed by hand or with a punch.
- The remaining cement is then removed with curettes, osteotomes, saws, and burrs. Reverse curettes, commonly used in hip revision surgery, can be useful in removing cement from the canal.

**FEMORAL COMPONENT REMOVAL**

- The prosthesis–cement interface is targeted in cemented components.
- The prosthesis–bone interface is targeted in uncemented components.
- The target interface is disrupted with a thin osteotome or saw with careful protection of the soft tissues (TECH FIG 3A).
TECH FIG 3 • A. The femoral component–cement interface is disrupted with an osteotome. The osteotome should be inserted parallel to the component. Smaller-width osteotomes can be used at the interface of the chamfer cuts and around distal pegs. Curved or angled osteotomes are helpful to work the interface of the posterior condyles. B. It should be possible to remove the femoral component easily by hand or with light taps from a punch. If the component is not extracted with gentle force, then further work with the osteotomes is needed.

- In general, use of Gigli saws results in the removal of more bone than is seen with the meticulous use of osteotomes.
- The interfaces should be worked from the medial and lateral sides rather than attempting to traverse the entire prosthesis with the instruments. This allows a more controlled division of the interface and minimizes iatrogenic bone loss.
- Care is taken to direct the instruments parallel to the component to avoid removing additional bone unnecessarily.
- Narrow osteotomes are used for the chamfer cuts and for prostheses where there are pegs at the distal aspect of the component.
- The posterior condylar interface can be disrupted with a curved or angled osteotome.
- It should then be possible to remove the implant easily by hand or with light taps from a punch set on the anterior flange (TECH FIG 3B). Alternatively, an extraction device that grasps the distal aspect of the femoral component can be used. The key point is gentle removal of the implant. Excessive force may result in unnecessary bone loss or fracture.
- The remaining cement is then removed with curettes, osteotomes, saws, and burrs.

PATELLA COMPONENT REMOVAL

- The removal of a well-fixed polyethylene component should be done only after thoughtful consideration. The remaining patella bone stock often is thin and osteopenic with one or several stress-risers from previous fixation pegs.
- The prosthesis–cement interface is targeted in cemented components.
- The prosthesis–bone interface is targeted in uncemented components.
- The target interface is disrupted with a thin sawblade (TECH FIG 4A).
- All polyethylene components can be removed with a sawblade, and the pegs subsequently burred (TECH FIG 4B). Cementless components may require the use of a metal cutting disc to sever the pegs from the plate. A pencil-tip burr can then be used to remove the pegs.
- Any remaining cement is removed with curettes, saws, and burrs.

TECH FIG 4 • A. The patella button is removed with a thin sawblade. The pegs remain embedded in the cement. B. A pencil-tip burr is used to lever the polyethylene pegs out of the cement mantle. The burr is advanced into the polyethylene and stopped; the polyethylene is then easily levered out of the cement mantle. A larger burr is then used to remove the remaining cement mantle.
STEMMED IMPLANT REMOVAL

- Stemmed implants usually can be removed once the fixation between the condylar portion of the femoral component and the tray portion of the tibial component has been separated from the bone.
- Preoperative planning should take into consideration the use of stemmed implants, which may complicate extraction of the component.
- Some designs allow for disassembly of the stem from the remainder of the implant.
- Metal cutting burrs and discs may be necessary to separate the condylar portion of the femoral implant or the keel portion of the tibial implant from the stem. The stem can then be removed with trephine reamers, burrs, or ultrasonic tools. Some companies may make special extraction devices available to assist in removal of the stem.
- Rarely, it may be necessary to perform an osteotomy to extract particularly difficult stems.

COMPLICATIONS

- Bone loss
- Fracture
- Ligament disruption
- Tendon disruption

REFERENCE

DEFINITION
- Obtaining adequate anterior exposure of the knee can be difficult using standard approaches during revision total knee arthroplasty (TKA).
- The options available for dealing with difficult exposure include extensor mechanism snip (done 5 to 8 cm proximal to the superior pole of the patella), V-Y quadriceps turndown, and tibial tubercle osteotomy.
- Tibial tubercle osteotomy is performed to obtain an extensile exposure of the knee during difficult revision TKA.
- An osteoperiosteal segment—which includes the tibial tubercle and upper tibial crest—is elevated to relax the extensor mechanism and allow safe eversion of the patella.
- The technique was first described by Dolin in 1983, but subsequently was modified and popularized for exposure in revision TKA by Whiteside.

ANATOMY
- The extensor mechanism consists of the quadriceps muscles (ie, rectus femoris, vastus lateralis, vastus medialis, and vastus lateralis), quadriceps tendon, patella, and patellar tendon.
- The quadriceps muscle inserts into the patella via the quadriceps tendon and then into the tibial tuberosity via the patellar tendon.
- Tendinous fibers of the vastus medialis and vastus lateralis form the medial and lateral patellar retinaculae, respectively, which together reinforce the capsule of the knee joint anteriorly (FIG 1A).

PATHOGENESIS
- Adequate anterior exposure of the distal femur and tibial plateau during revision TKA is crucial for gentle soft tissue handling, safe implant removal, recognition of bone defects, and correct placement of revision components.
- During revision TKA, adhesions and fibrosis within the extensor mechanism restrict eversion of the patella and limit exposure.
- A medial parapatellar arthrotomy, combined with intra-articular excision of the fibrous pseudocapsule, allows eversion of the patella in most cases.
- Inadequate exposure with continued forceful retraction of the extensor mechanism risks avulsion of the patellar ligament from the tibial tubercle.

NATURAL HISTORY
- Avulsion of the patellar ligament is a serious complication during revision TKA, because it results in prolonged immobilization, extensor lag, and a poor functional outcome.
- To avoid this complication, an extensile exposure is required to relax the extensor mechanism and allow safe eversion of the patella.

FIG 1 • A. The extensor mechanism of the knee. Note that the medial and lateral patellar retinaculae originate proximally from the tendinous fibers of the vastus medialis and lateralis muscles, respectively. B. The tibial tuberosity. The distal “rough” area is subcutaneous and palpable. The patellar ligament is attached to the proximal “smooth” area.
Three options for obtaining such an extensile exposure during revision TKA are quadriceps snip, V-Y quadriceps turn-down, and tibial tubercle osteotomy.

Tibial tubercle osteotomy is preferred because it has a lower incidence of extensor lag and quadriceps weakness compared to a V-Y quadriceps turn-down.1,5

PATIENT HISTORY AND PHYSICAL FINDINGS

A history of joint stiffness and complications after primary TKA (eg, arthrofibrosis, infection, hematoma) should alert the surgeon regarding potential difficulties with exposure during revision TKA.

Physical findings indicating possible difficulty with exposure during revision TKA include multiple scars, reduced active and passive knee range of movement, a tight posterior cruciate ligament, and patella baja.

IMAGING AND OTHER DIAGNOSTIC STUDIES

Standing anteroposterior and lateral radiographs of the knee usually are adequate in planning for extensile exposures during revision TKA.

The radiographs are specifically inspected for tibial osteopenia and osteolysis, both of which are relative contraindications for tibial tubercle osteotomy.

SURGICAL MANAGEMENT

A tibial tubercle osteotomy is indicated when there is any concern regarding patellar tendon avulsion despite adequate initial soft tissue release, as discussed later in this chapter.

Preoperative Planning

Exposure is considered preoperatively: the history and physical findings should alert the surgeon regarding the potential need for extensile exposures during revision TKA.

Previous operative records and radiographs are studied to identify the initial approach during primary TKA, design of the implanted components to be removed, and potential problems during implant removal.

The quality of skin overlying the tibial tubercle should be assessed. In patients with multiple scars, the most recent, appropriate, healed scar is used, but in many situations where tibial tubercle osteotomy is indicated, it may be necessary to consult with a plastic surgical team to plan soft tissue coverage (FIG 2).

Positioning

- The patient is positioned supine on the operating table.
- A tourniquet is sited around the upper thigh, and the leg is exsanguinated before inflation.
- A clamp is positioned laterally to stabilize the lower leg when the knee is flexed.
- A sandbag is positioned distal to the foot to prevent the lower leg from sliding during surgery.

Approach

A medial parapatellar approach is used whenever possible, because extensile exposures are most easily incorporated proximally (V-Y quadriceps turn-down) and distally (tibial tubercle osteotomy).

If the patella cannot be everted following medial parapatellar arthrotomy, the following soft tissue releases are performed sequentially before considering a tibial tubercle osteotomy.

- **Medial release:** The dissection is carried medially around the proximal tibia with subperiosteal elevation of the medial retinaculum and deep medial collateral ligament around to the semimembranosus insertion (TECH FIG 1A, B). This allows external rotation of the tibia and relaxes the extensor mechanism (TECH FIG 1C, D).
- **Lateral gutter release and pseudocapsule excision.**
  - **Superior to the patella,** the suprapatellar pouch is freed by dividing the underlying adhesions tethering the extensor mechanism to the anterior femur (TECH FIG 1E).
  - **Lateral to the patella,** adhesions in the lateral gutter tethering the extensor mechanism are divided (TECH FIG 1F).
  - ** Inferior to the patella,** the interval between the patellar tendon anteriorly and fat pad posteriorly is identified and the intervening pseudocapsule excised distally to the insertion of the patellar tendon (TECH FIG 1G, H).
- If the patella still cannot be everted, a tibial tubercle osteotomy is performed to reduce the risk of patellar tendon avulsion from forceful retraction of the extensor mechanism.

![Skin incisions. A. Previous skin incisions marked. B. Midline incision through most recent, healed scar.](image-url)
TECH FIG 1 • Initial soft tissue release to relax extensor mechanism and allow eversion of the patella. A. Subperiosteal elevation of medial retinaculum. B. Subperiosteal medial release to semimembranosus insertion. C,D. The pseudocapsule is completely excised medially to free the medial gutter. E,F. First the suprapatellar pouch, with the lateral gutter, is freed from underlying adhesions. G,H. Next, the pseudocapsule inferior to the patella is excised.
TIBIAL TUBERCLE OSTEOTOMY

- The skin incision is extended 8 to 10 cm below the tibial tubercle.
- The periosteum is vertically incised 1 cm medial to the tibial tubercle.
- An osteotomy site measuring 6 cm long, 2 cm wide, and 1 cm thick, which includes the tibial tubercle and anterior tibial crest, is marked with electrocautery (TECH FIG 2A,B).
- The 6-cm medial, vertical limb of the osteotomy is tapered distally to prevent a stress riser.
- The 2-cm horizontal limb proximal to the insertion of the patellar tendon resists proximal migration of the osteotomized segment.
- The proposed medial, lateral, and proximal osteotomy cuts are perforated using a drill (TECH FIG 2C).
- Sequential osteotomes are used to transect the medial tibial crest and separate the osteotomized segment from the tibia.
- The lateral cortex is transected through the osteotomy, but the lateral periosteum and soft tissues are left attached to the elevated segment to act as a “hinge,” allowing eversion of the extensor mechanism.

TECH FIG 2 • Tibial tubercle osteotomy. A. The distal cut is tapered to prevent a stress riser. Proximally, the step-cut reduces the risk of proximal migration. B. The medial, vertical limb should be at least 6 cm long. C. The medial cortex is perforated with a drill, and the drill is passed through the lateral cortex to create corresponding perforations in the lateral cortex that will allow the osteoperiosteal segment to be “hinged” around the lateral soft tissue attachments. The proximal osteotomy cut is perforated, and sequential osteotomes are used to elevate the osteotomy.

REATTACHMENT OF OSTEOTOMY WITH WIRES

- In our preferred technique, three 18-gauge stainless steel wires are inserted and left untied before the final components are implanted.
- The most proximal wire is passed through the osteotomized segment and through a drilled hole in the medial tibial cortex.
- The two distal wires are passed around the osteotomized segment and through drilled holes in the medial and lateral tibial cortices (TECH FIG 3).
- The wires are twisted until tight, cut, and angled 45 degrees posteromedially to prevent soft tissue irritation.

TECH FIG 3 • Reattachment of osteotomy with wires. The most proximal wire is passed through the osteotomized segment to prevent proximal migration; the two distal wires are passed around the osteotomy segment. Wires are cut and angled posteromedially to prevent soft tissue irritation.
**PEARLS AND PITFALLS**

**Indications**
- Anticipate need for extensile exposure preoperatively.
- Anticipate need for soft tissue coverage with plastic surgery.

**Initial exposure**
- Medial parapatellar approach.
- Medial release, meticulous lateral gutter release, and excision of pseudocapsule before tibial tubercle osteotomy.

**Tibial tubercle osteotomy**
- Use a long (6–8 cm) osteoperiosteal segment.
- Use a proximal step-cut to prevent proximal migration.
- Taper distally to avoid stress risers.
- Use sequential osteotomes, not an oscillating saw.

**Reattachment of osteotomy**
- Anatomic fixation of the osteotomized segment is critical to ensure union of the osteotomy.
- At least one wire is passed through the osteotomy fragment to prevent proximal migration.

**POSTOPERATIVE CARE**
- If fixation of the tibial tubercle osteotomy is adequate, weight bearing is permitted as tolerated with unrestricted range of movement in a hinged knee brace.
- If fixation is not adequate, the patient can bear weight as tolerated with the knee locked in full extension in a brace until there is radiologic evidence of union.

**OUTCOMES**
- Whiteside\(^8\) reported good results using a tibial tubercle osteotomy to gain extensile exposure during 136 TKAs, of which 110 were revision procedures. At 2-year follow-up, the mean postoperative range of movement was 94 degrees, with a 1.5% incidence of extensor lag. Three tibial shaft fractures and two avulsions of the tibial tubercle were reported in this series, but no non-unions.
- Mendes\(^6\) reported 87% good-to-excellent results (based on the Knee Society Score) in 64 patients in whom a tibial tubercle osteotomy was used for extensile exposure during revision TKA. At an average follow-up of 30 months, the mean postoperative range of movement was 107 degrees, with a 4.5% incidence of extensor lag. One fracture of the tibia, no tibial avulsions, and two non-unions of the osteotomy were reported in this series.
- Barrack\(^1\) reported a significantly lower incidence of extensor lag following tibial tubercle osteotomy when compared to V-Y quadriceps turndown, although outcome scores were similar for both groups at the 4-year follow-up.
- Biomechanical studies show that although reattachment of an osteotomy with screws has greater fixation strength than cerclage wires, placement of screws around revision tibial component stems is difficult.\(^2\) Cerclage wires are easier to place and still provide solid fixation, especially when combined with a proximal step-cut osteotomy.
- High rates of fixation failure with tibial tubercle osteotomy most likely are due to the use of small (<3 cm) osteoperiosteal fragments and failure to maintain lateral soft tissue attachments in continuity with the osteotomized segment.\(^9\)

**COMPLICATIONS**
- Extensor lag\(^1,6,8\)
- Tibial fracture\(^6,8\)
- Tibial tuberosity avulsion\(^7,8\)
- Non-union of osteotomy\(^6\)
- Metalwork removal\(^7,8\)
REFERENCES

DEFINITION

- Gaining exposure during revision total knee arthroplasty (TKA) and primary TKA for the ankylosed knee can be challenging.
- Although over 90% of revision TKA procedures can be performed through a standard surgical approach, the surgeon should be familiar with more extensile techniques in case one of those must be used to avoid extensor mechanism disruption.4
- If adequate exposure is not obtained, a graduated approach is necessary.
- Quadriceps snip is used most commonly, followed by tibial tubercle osteotomy or V-Y quadriceps turndown.
- Although it may be possible to perform a prosthetic implantation without using an extensile exposure in the ankylosed knee, quadriceps contracture can limit extensor mechanism excursion, leading to poor postoperative flexion.
- V-Y quadricepsplasty may be performed after prosthetic insertion to improve flexion.6

STANDARD APPROACH

- Any skin incisions from previous procedures are clearly marked before skin preparation begins.
- Although a straight, midline anterior incision is preferred, because the vascular supply to this skin is primarily from the medial side, the most lateral useable incision is chosen. Previous skin incisions are intersected at an angle of no less than 60 degrees.
- Thick flaps are developed that include the superficial fascia.
- A medial parapatellar arthrotomy is then made at the junction of the medial and central thirds of the quadriceps tendon.
- Subperiosteal dissection of the tibia is then extended from the tibial tubercle to the posteromedial corner, including release to the semimembranosus insertion.
- A suprapatellar pouch, as well as the medial and lateral gutters, is then reestablished, all adhesions are released, and a thorough synovectomy is performed.
- All peripatellar scar tissue is removed.
- The knee is then gently flexed. The tibia is externally rotated and subluxed anteriorly, thereby reducing tension on the extensor mechanism.
- If the extensor mechanism is still under too much tension, dissection is carried distally and the superficial medial collateral ligament is released, followed by lateral retinacular release, making sure to preserve the lateral superior geniculate.
- If adequate exposure still is not possible, a quadriceps snip is performed, as described in Chapter AR-27.
- In most revision TKAs, adequate exposure can be obtained with these maneuvers.4

TIBIAL TUBERCLE OSTEOTOMY

- Tibial tubercle osteotomy (see Chap. AR-26) is chosen in cases with difficult stem or cement extraction or patients with patella baja.3

QUADRICEPS TURNDOWN

- The quadriceps tendon is exposed proximally to the insertion of the vastus lateralis and medialis muscles.
- The medial parapatellar arthrotomy is extended proximally to the insertion of the vasti.
- The quadriceps is then incised distally and laterally at an angle of about 45 degrees along the insertion of the vastus lateralis (TECH FIG 1).
- This inverted V creates a distally based flap that includes the patella. Essentially, the medial incision is connected to the lateral release.
- Care should be taken to preserve the lateral superior geniculate artery.
- The patella is now “turned down” anterolaterally, providing excellent exposure to the joint.
V-Y QUADROPLASTY

- The quadriceps is repaired in situ with multiple interrupted no. 2 nonabsorbable sutures, and ROM is assessed.
- If ROM is acceptable, closure is completed, leaving the lateral retinacular release open.
- If increased passive ROM is desired, the V is converted to an inverted Y.
- From 1% to 2% of advancement can be performed.
- The knee is flexed, and sutures or clamps are placed along the apex of the Y.
- Once appropriate lengthening is established, no. 2 nonabsorbable sutures are used to close the medial side of the quadriceps mechanism.
- The lateral retinacular release is left open.
- The lateral limb of the quadricepsplasty is covered by closing the quadriceps mechanism to the superficial fascia of the vastus lateralis (TECH FIG 2).
- The maximum flexion of the knee that will not put undue tension on the repair is recorded prior to routine skin closure.

PEARLS AND PITFALLS

- The patient and family members should be counseled preoperatively regarding the possibility that this approach may be required and prepared for the subsequent need for bracing.
- Intraoperatively, a graduated approach is necessary, starting with a medial parapatellar approach with lateral release, advancing to quadriceps snip, and lastly to osteotomy or V-Y turndown as needed.
- Preserve the superior lateral geniculate.
- Do not be aggressive with range of motion (ROM), particularly during the first 2 weeks.

POSTOPERATIVE CARE

- One disadvantage of V-Y quadricepsplasty is that it is necessary to modify postoperative rehabilitation.
- Maximum passive flexion to avoid tension on the repair is determined intraoperatively, after capsular closure. This is not exceeded in the first 2 weeks.
- The patient is placed in an immobilizer immediately postoperatively.
- A hinged brace is fitted after the first dressing change. A flexion stop is used for the first 2 weeks.
- Passive knee extension and active knee flexion are done for 6 weeks.
- Partial weight bearing is required for 6 weeks.
- The brace is locked in extension at night and with ambulation until the extensor lag is less than 15 degrees.

**OUTCOMES**
- Knee scores are similar to those of patients who have had revision TKA and reflect the difficulty of knees that need this procedure.
- In one study⁴ that compared patients who had had quadriceps turndown and tibial tubercle osteotomy to patients whose revision TKAs were performed with routine exposure, patients in the quadriceps turndown and tibial tubercle osteotomy groups had equivalent postoperative scores, which were significantly lower than those of patients in the routine exposure revision group. The turndown group had a higher increase in arc of motion than the osteotomy group, but they also had a higher degree of extension lag. The turndown group also had a lower percentage of patients who considered their surgery unsuccessful in relieving pain and return of function, and a lower percentage of patients who had difficulty with kneeling and stooping.⁵
- In a mixed population of primary and revision TKA, Cybex testing revealed that the quadriceps was weaker on the VY quadricepsplasty side, but this did not reach statistical significance. Only 5 of 14 patients had extensor lag greater than 5 degrees, with active extension lag averaging 4 degrees (range 0 to 20 degrees).⁷

**COMPLICATIONS**
- Patellar osteonecrosis was observed in 8 of 29 patients with quadriceps turndown in one study.⁵ It is critical to preserve the superior lateral geniculate artery.
- One case of minor wound dehiscence also was reported in a hemophiliac patient during manipulation under anesthesia after TKA using VY quadricepsplasty.

**REFERENCES**
DEFINITION
- Patellar tendon rupture following total knee arthroplasty (TKA) is a devastating complication with a prevalence of 0.17% to 2.5%.\(^1,2\)
- The patellar tendon is involved more commonly (0.22%) than the quadriceps tendon (0.1%).
- Despite reports of encouraging results following direct repair in native knees, attempts at primary repair following TKA rarely are successful in restoring extensor function.

ANATOMY
- The patellar tendon connects the tibia and the patella. It originates at the inferior pole of the patella and inserts onto the tibial tuberosity. It is about 5 to 6 cm long and 3 cm wide.
- The extensor mechanism of the knee begins proximally as the quadriceps femoris muscle.
- Anteriorly, the fibers of the rectus femoris tendon traverse the patella and insert on the tibial tubercle inferior to the patella as the patellar tendon.
- The fibers of the vastus lateralis muscle expand to the superolateral border of the patella and proximal tibia to form the lateral retinaculum.
- The fibers of the vastus medialis muscle insert into the superomedial border of the patella and tibia to form the medial retinaculum.

PATHOGENESIS
- The etiology of extensor mechanism disruption is multifactorial.
- Factors associated with patellar tendon rupture include:
  - Difficult exposure in a stiff knee
  - Extensive release of the patellar tendon at the time of surgical exposure
  - Manipulation for the treatment of limited motion
  - Revision TKA
  - Malrotation of the components
  - Overly aggressive postoperative physical therapy
  - Distal realignment procedures
- Some comorbid conditions may predispose patients to extensor mechanism rupture:
  - Systemic corticosteroid use
  - Diabetes mellitus
  - Chronic renal insufficiency
  - Parkinson disease
  - Gout
  - Morbid obesity
  - Multiple intra-articular corticosteroid injections

NATURAL HISTORY
- Patellar tendon ruptures are difficult to treat.
- Despite encouraging results reported following direct repair in native knees, attempts at primary repair following TKA rarely are successful in restoring extensor function.
- Augmentation with autograft or allograft tissue often is required.

PATIENT HISTORY AND PHYSICAL FINDINGS
- Patients with rupture of the patellar tendon present with localized pain, palpable loss of patellar tendon tension during active knee extension, extensor lag, and hemarthrosis.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- Anteroposterior (AP) and lateral radiographs of the knee should be obtained.
- Comparison with either immediate postoperative or preoperative films is helpful to establish the diagnosis of a complete rupture of the patellar tendon.
- Patella alta will be present and can be evaluated by comparison with earlier radiographs (FIG 1).

DIFFERENTIAL DIAGNOSIS
- Patellar fracture
- Quadriceps rupture
- Patella contusion
- Patellar tendinitis
- Prepatellar bursitis

NONOPERATIVE MANAGEMENT
- There is very little role for nonsurgical treatment of patellar tendon ruptures.
- For the rare person with a partial patellar tendon tear with maintenance of patellar height, cast or brace immobilization in
full extension for 6 weeks followed by physical therapy to regain motion and strength may be appropriate. Progress must be slow to allow for tendon-to-bone healing. Strengthening exercises should be delayed for at least 3 months.

- **Contraindications for surgical reconstruction include:**
  - Infection
  - Inability to comply with postoperative immobilization and the physical therapy program
  - For these rare instances, cast or brace immobilization in full extension for 6 to 8 weeks followed by a physical therapy program to regain motion and strength may be appropriate.
  - Progress must be slow, and strengthening exercises should be delayed for at least 3 months.

### SURGICAL MANAGEMENT

- A deficient extensor mechanism in association with a TKA poses a very challenging problem.
- Direct suture or staple repair alone is often unsuccessful.
- Options for management of patellar tendon rupture after TKA include direct repair, with augmentation with an autogenous semitendinosus tendon graft; an Achilles or whole patellar tendon allograft; or a synthetic ligament.
- In this chapter, we describe the technique that we use in our institution, consisting of reconstruction with Achilles tendon allograft with or without augmentation with an autogenous semitendinosus tendon graft.

#### Preoperative Planning

- Initial evaluation of the patient
  - History
  - Physical examination of the knee
  - Radiographs
- Previous operative reports should be obtained. The surgeon should be ready to perform revision surgery of any of the components if there is evidence of malrotation or malalignment.
- Order the Achilles tendon allograft.
  - Fresh-frozen allografts are preferable to freeze-dried allografts
  - Before anesthesia induction, the allograft is inspected visually to ensure that the specimen is adequate. A distal calcaneus bone allograft measuring at least 3 cm must be attached to the Achilles tendon.

### Positioning

- We use a laminar-flow operating room.
- The patient is placed supine on a radiolucent table.
- A regular pneumatic tourniquet around the thigh is used.
  - Alternatively, if the incision extends too proximally, a sterile tourniquet can be used.
- The leg is prepared and draped in the standard sterile fashion for joint replacement surgery.
- Fluoroscopic equipment is in the room with a technician available in case it becomes necessary to use it: eg, for judgment of the joint line, preparation of the tibial box, or placement of the screws to avoid the tibial component.
- Previous incisions are marked (FIG 2).
- The pneumatic tourniquet is inflated (usually to 250 mm Hg) after the leg has been exsanguinated with an Esmarch bandage.

#### APPROACH

- Because the patient already has had a total knee replacement in the past, the previous incision should be used.
- The dissection is carried down in the midline with conservative elevation of skin and subcutaneous flaps.
- The retinaculum and extensor mechanism are exposed.
- The tendon rupture is evaluated.
- A midline incision is performed through the patellar tendon.
- Medial and lateral flaps of retinaculum are created.
- The joint is drained of any hematoma and irrigated using pulsatile lavage (TECH FIG 1).
**PRIMARY REPAIR**

- Create two parallel tunnels through the patellar bone (TECH FIG 2A).
- Use heavy no. 2 nonabsorbable suture in a running, locked fashion (TECH FIG 2B,C).
- The repair is augmented with the use of no. 1 Vicryl in an interrupted figure 8 technique (TECH FIG 2D).

**TECH FIG 2 • A.** Two parallel tunnels are made through the patellar bone. B,C. A heavy no. 2 nonabsorbable suture is used to perform the primary repair in a running, locked fashion. D. The repair is augmented with the use of no. 1 Vicryl in an interrupted figure 8 technique.

**PREPARATION OF THE TIBIA AND ALLOGRAFT**

- A small saw is used to make a rectangular cavity 2.5 cm × 1.5 cm × 1 cm in the proximal part of the tibia slightly distal and medial to the original insertion site of the patellar tendon (TECH FIG 3).
- The Achilles tendon allograft is then prepared.

**TECH FIG 3 • A.** A rectangular cavity is made in the proximal part of the tibia.

**PREPARATION AND INSERTION OF THE CALCANEAL BONE BLOCK**

- The calcaneal bone block is cut to match the created rectangular space in the proximal tibia (TECH FIG 4A,B).
- The bone block is gently impacted into the proximal tibia (TECH FIG 4C).
- Two 4.5-mm screws, angled to avoid the tibial component, are used to secure the bone block to the tibia (TECH FIG 4D,E).
TECH FIG 4 • A,B. The calcaneal bone is cut to match the created rectangular space in the proximal tibia. C. The calcaneal bone block is gently impacted into the proximal tibia. D,E. The calcaneal bone block is fixed to the proximal tibia with the use of two 4.5-mm screws.

TECH FIG 5 • A. The Achilles tendon allograft is cut to obtain a rectangular patch. B. The rectangular patch is used to augment the attempted primary repair. C,D. The Achilles graft is attached to the underlying extensor mechanism.

**PLACEMENT OF THE ALLOGRAFT**

- The Achilles tendon is draped over the anterior tibia and patella while the knee is positioned in full extension.
- Apply enough tension to the allograft to keep it taut and unwrinkled.
- The most proximal part of the Achilles tendon allograft is cut to obtain a rectangular patch (TECH FIG 5A).
- The rectangular patch is used to augment the attempted primary repair, and is sutured in place with no. 1 Vicryl, in an interrupted fashion (TECH FIG 5B).
- The Achilles graft is attached to the underlying extensor mechanism with no. 2 nonabsorbable sutures, in an interrupted fashion (TECH FIG 5C,D).
WOUND CLOSURE
- Subcutaneous tissues are closed in routine fashion.
- The skin is closed with staples and a compression dressing applied. The tourniquet is deflated.
- A knee immobilizer is applied with the knee in extension.
- Postoperative anteroposterior and lateral radiographs of the knee are obtained in the postoperative care unit (TECH FIG 6).

PEARLS AND PITFALLS

<tr>
<td>Before anesthesia induction, visually inspect the allograft to ensure that it is adequate, with at least 3 cm distal calcaneus bone allograft attached to the Achilles tendon.</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

POSTOPERATIVE CARE
- The knee is immobilized in full extension for 4 weeks, using a hinged knee brace locked in 0 degrees of extension.
- Staples are removed 3 weeks after surgery.
- A brace is used to allow 30 degrees of flexion for 4 weeks.
- Then a brace is used to allow 60 degrees of flexion for 4 more weeks.
- A progressive controlled increase in flexion and strengthening exercises is allowed after 12 weeks.

OUTCOMES
- Short-term results are encouraging, but residual extensor lags of 5 to 20 degrees or more are common.3,4
- Longer-term follow-up of patients with Achilles allograft reconstruction of patellar tendon ruptures is required.

COMPLICATIONS
- Graft failure
- Infection

REFERENCES
DEFINITION

At less than 90 degrees of active knee flexion, a total knee arthroplasty (TKA) has inadequate range of motion (ROM) for performing many activities of daily living. The required ranges of motion for daily activities are as follows:

- 67 degrees of flexion for normal gait on level ground
- 83 degrees of flexion to climb stairs
- 90 to 100 degrees of flexion to descend stairs
- 93 degrees of flexion to stand from a standard-height chair
- 105 degrees of flexion to tie a shoe

Flexion contractures can be equally disabling: a flexion contracture of more than 15 degrees usually is considered pathologic, because it greatly inhibits normal gait.

ANATOMY

The primary impediments to exposure of the revision TKA, particularly a stiff TKA, are the extensor mechanism and the patella. The exposure can be thought of as a progressive release or “unleashing” of the extensor mechanism.

The four tethers of the extensor mechanism (FIG 1) are:

- Proximal: quadriceps tendon and musculature
- Medial: medial joint capsule and retinaculum with the insertion of the vastus medialis
- Lateral: lateral joint capsule and retinaculum with the insertion of the vastus lateralis
- Distal: patellar tendon

The blood supply to the patella is provided by an anastomotic ring of vessels supplied by the geniculate arteries. It is important to try to avoid complete devascularization of the patella, because avascular necrosis can occur.

The blood supply to the skin overlying the knee travels from the deeper tissues up through the superficial fascia and does not run superficially. If skin flaps are required at the time of surgery, they must be full-thickness, therefore, to avoid skin necrosis.

PATHOGENESIS

Many potential causes for stiffness following TKA exist, and multiple mechanisms may act in concert in a given patient, resulting in suboptimal ROM.

- Poor perioperative pain control or suboptimal physical therapy. In rare cases, a chronic regional pain syndrome develops, characterized by severe pain, cutaneous hypersensitivity, vaso-motor disturbance, and stiffness.
- Technical issues related to the original surgical procedure may play a role.

![FIG 1](image-url) • Anterior view of the knee showing the patella, patellar tendon, quadriceps tendon, vastus medialis oblique muscle, and vastus lateralis.
Femoral component
- Oversized: leads to tightness in flexion
- Internally rotated: leads to patellar maltracking or an asymmetric flexion gap
- Inadequate distal femoral resection: leads to tightness in extension and a potential flexion contracture
- Over-resection of the distal femur: requires a thicker polyethylene insert to obtain stability, thereby leading to tightness in flexion
- Inadequate removal of posterior femoral osteophytes: leads to tenting of the posterior capsule and flexion contracture or osteophytes that can impinge on the tibial polyethylene insert, limiting flexion
- Anterior placement of the femoral component: leads to "over-stuffing" of the patellofemoral joint

Tibial component
- Most commonly, inadequate or reverse slope of the tibial cut, which leads to tightness in flexion; internal rotation, which leads to patellar maltracking; oversized component, which leads to soft tissue impingement and pain
- Elevation of the joint line (particularly if >1 cm): leads to poor ROM secondary to altered patellofemoral joint mechanics
- Inadequate resection of the tibia: leads to tightness in both flexion and extension

Patellar component
- Under-resection of the patella: leads to overstuffing of the patellofemoral articulation. The native patella–prosthetic composite should be equivalent in thickness to the patella before resection.
- Excessive patellar resection: leads to weakness of the extensor mechanism with initial extensor lag and eventual flexion contracture
- Inadequate medialization of the component: leads to patellar maltracking
- Inadequate removal of lateral patellar osteophytes: leads to impingement and pain
- Ligamentous imbalance: flexion-extension mismatch (typically too tight in flexion, particularly with a cruciate-sparing design) or varus-valgus instability
- Poor component fixation: failed ingrowth of cementless components or inadequate cement mantle around cemented components, resulting in persistent pain that inhibits physiotherapy

Patient-related factors
- Poor preoperative ROM (the best predictor of postoperative ROM is preoperative ROM)
- Genetic predisposition to scarring and stiffness
- A history of previous surgery on the knee that has led to stiffness or a patella baja (shortening of the patellar tendon)
- Noncompliance with physical therapy
- Obesity (soft tissue envelope of the posterior thigh and leg limits flexion)
- Stiffness or arthritis of the ipsilateral hip
- Deep infection
- Heterotopic ossification

NATURAL HISTORY
- The natural history of the stiff TKA is poor. Even with time, patients’ ROM rarely improves enough to positively impact their gait pattern, and chronic pain develops.
- Flexion contractures are equally poorly tolerated, as is inadequate flexion. Flexion contractures greater than 15 degrees limit the ability to stand up straight and cause substantial fatigue when walking.
- Patients with only mild stiffness (ie, ROM near 90 degrees) may improve slightly (5 to 10 degrees) in the first 2 years after surgery, reaching a level of flexion that is tolerable for most activities of daily living.

PATIENT HISTORY AND PHYSICAL FINDINGS
- The history is a critical part of the evaluation to determine which of the factors listed under Pathogenesis have led to stiffness; in most cases, more than one factor is at work.
- Direct questions should be asked to determine whether pain control was adequate in the postoperative period.
- Did the patient have severe pain postoperatively that limited his or her ability to perform physical therapy?
- For how long postoperatively did the patient require narcotics? Is the patient still taking narcotics and still in severe pain?
- Does the patient have hypersensitivity of the skin overlying the incision or other complaints that suggest neurogenic pain or a chronic regional pain syndrome?
- How was the patient’s stiffness addressed postoperatively?
- Did he or she undergo a manipulation under anesthesia (MUA) postoperatively?
- Has he or she undergone any other operative procedures (eg, open or arthroscopic release) in an attempt to improve ROM?
- Does any element of the history suggest infection?
- Wound drainage that persisted for more than a few days after surgery
- The use of antibiotics for more than 24 hours postoperatively
- Persistent pain that is of a different character than the pain the patient had before the surgery

Inspect the skin for the presence of a past or present sinus, indicating infection. Densely adherent skin is much harder to close and may represent a higher risk for necrosis.
- Evaluate the patient’s ROM. Flexion of less than 90 degrees and a flexion contracture of more than 15 degrees are considered pathologic. Loss of ROM affects gait and ability to perform activities of daily living.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- Standing anteroposterior (AP), lateral, and patellar radiographs should be obtained to identify component loosening, malposition, or improper sizing (FIG 2A).
- Patella baja and joint line position also should be noted (FIG 2B). Severe ligamentous imbalance may be readily apparent on the plain radiographs. Patellar maltracking also can be identified (FIG 2C), as can an unresurfaced patella, which may be causing pain that leads to stiffness.
- Serial radiographs often are helpful in confirming component loosening.
- A CT scan to determine femoral and tibial component rotation often is performed (FIG 2D–F). If component malposition is identified (eg, internal rotation), the components are revised.
Erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) level are obtained before every revision TKA. If either is elevated, an aspiration of the knee joint is obtained and sent for a cell count with differential and cultures, including aerobic, anaerobic, and acid-fast bacilli, and fungi. A white blood cell count above 3000 is considered consistent with infection. Patients must have been off antibiotics for at least 2 weeks before the knee aspiration. At the time of revision, additional cultures are taken from within the joint, and an intraoperative frozen section is taken from the synovial tissues. An average of more than 10 polymorphonuclear cells identified within tissue (and not fibrin) is consistent with infection.

Nuclear medicine studies, such as a triple-phase bone scan, occasionally are helpful in identifying subtle loosening but are not routinely obtained.

**DIFFERENTIAL DIAGNOSIS**
- Deep infection
- Component malposition (eg, internal rotation of the femur or tibia)
- Patellar maltracking or overstuffing of the patellofemoral joint
- Improper component sizing
- Ligamentous imbalance (eg, tightness in flexion)
- Component loosening
- Chronic regional pain syndrome

**NONOPERATIVE MANAGEMENT**
If the patient is seen early in the postoperative period (less than 6–12 weeks postoperatively), he or she can be managed with a combination of the approaches discussed in this section.

**SURGICAL MANAGEMENT**
- The decision to proceed with revision TKA for stiffness should be considered carefully and only after a full investigation as to the cause or causes of stiffness. The patient must be fully
informed of the risks of the procedure and educated that the ROM may not improve, even with further surgery. It is crucial to work with a pain management specialist and a physical therapist to ensure that stiffness does not recur postoperatively.

- Options for surgical management include:
  - Arthroscopic débridement with manipulation$^2,5,7,15$
    - This can be performed in highly selected patients with well-fixed, appropriately aligned components. The procedure is technically demanding, and the results reported in the literature are variable, with most studies showing mild improvements in ROM (15 to 30 degrees, on average).
    - The technique includes release of the posterior cruciate ligament (if present), clearing of scar from the suprapatellar region, and, typically, MUA once the scar has been cleared.
    - Flexion contractures are harder to address arthroscopically, but a posterior release can be performed using small, open, medial and lateral incisions.
  - Open arthrolysis with exchange of the modular polyethylene liner$^1,9,10,13$
    - This procedure also can be performed in selected patients with well-fixed, appropriately aligned components. It often is difficult to fully release the posterior capsule to treat flexion contractures, however, and it is unclear whether this technique has any benefit over arthroscopic release.
  - Revision TKA$^6,8,10,11,14$
    - Revision TKA is the most appropriate treatment for most patients. It allows for optimization of component alignment, size, and rotation, while providing the opportunity to restore the joint line.
    - It affords complete access to the posterior capsule to perform a capsulectomy and remove any retained osteophytes from the previous surgical procedure.
    - An additional benefit is the option of using a more constrained polyethylene insert, if desired, to optimize stability if extensive releases are performed.
    - If a large flexion contracture is being addressed, a flexion-extension mismatch often is present (ie, extension space smaller than the flexion space), and constrained and even hinged implants may be required.

Preoperative Planning

- The history, physical examination, plain radiographs, and CT scan (if obtained) are reviewed before a definite decision is made whether the components are to be removed or retained.
- The ESR, CRP, complete blood cell count, and culture results are reviewed to determine whether a deep infection is present.
- If any of the prosthetic components are to be retained, the operative note from the previous procedure must be reviewed to definitely identify manufacturer, model, and size so that appropriate, matching replacement implants and trials are available on the day of surgery.
- An examination under anesthesia confirms the limits of motion.

Positioning

- The operative extremity is draped free from the hip to the ankle, and a tourniquet is placed on the upper thigh.
- A bump placed underneath the ipsilateral hip assists in keeping the leg upright.
- A leg holder keeps the leg in the desired position for surgery.
- An elastic bandage placed on the lower leg defines the malleoli, which are used as a reference for tibial cut alignment (FIG 3).

Approach

- The workhorse approach for exposure in revision TKA is the medial parapatellar approach with complete excision of intra-articular scar tissue. This approach is useful for most revision TKAs.
  - In the stiff knee, however, a more extensile approach may be required.
  - If additional exposure is needed, a quadriceps snip can be performed.
  - This maneuver assists in freeing the proximal tether of the extensor mechanism, thereby improving exposure.
  - Benefits include relative simplicity of performance and repair, no need to alter postoperative rehabilitation protocols, and clinical results that have been shown to be equivalent to those in patients who have undergone a revision TKA without a snip.
  - If a more extensile exposure is needed, the extensor mechanism can be completely released proximally with a V-Y quadricepsplasty (see Chap. AR-27) or distally with a tibial tubercle osteotomy (see Chap. AR-26).

MEDIAL PARAPATELLAR ARTHROTOMY WITH COMPLETE INTRA-ARTICULAR RELEASE

- Skin incision
  - Previous skin incisions are used whenever possible.
  - Avoid parallel incisions. If choosing among multiple previous incisions, the most lateral one is selected, because the blood supply is derived predominantly from the medial side.
  - Full-thickness flaps are raised, if required.

- The arthrotomy extends from the apex of the quadriceps tendon, around the medial aspect of the patella and just medial to the tibial tubercle (TECH FIG 1A).
- On entering the joint, large amounts of scar typically are encountered (TECH FIG 1B); these prevent proper exposure and contribute to stiffness.
A medial release is performed with electrocautery by subperiosteally releasing a continuous soft tissue sleeve all the way to the posteromedial corner of the tibia and the semimembranosus insertion (TECH FIG 1C).

This allows for external rotation of the tibia, which relaxes the extensor mechanism and improves exposure.

The junction between scar and the extensor mechanism is identified (TECH FIG 1D). The scar is meticulously removed from underneath the extensor mechanism laterally (TECH FIG 1E) and from underneath the joint capsule medially until the medial and lateral gutters have been re-established (TECH FIG 1F).

A thin layer of soft tissue is left on the distal femur to prevent excessive bleeding and also to prevent the extensor mechanism from becoming readherent in this area.

The scar tissue is carefully cleared from behind the patellar tendon by identifying the interval between the patellar tendon and the scar behind it to release the patellar tendon from the proximal tibia.

At this point, the modular polyethylene liner is removed to allow for patellar eversion or subluxation. In most cases, patellar subluxation is preferred, because it places less tension on the extensor mechanism and provides adequate exposure in most cases.

If difficulty is encountered, soft tissue can be peeled off the lateral border of the patella to make it more mobile, and any osteophytes that are present can be removed.

If exposure still cannot be accomplished, a formal lateral retinacular release may be required.

This release involves a full-thickness division of the capsule along the lateral border of the patella from the proximal tibia (just lateral to the patella tendon) to the vastus lateralis.

A lateral release performed from the inside out eliminates the need to raise additional skin flaps.

**QUADRICEPS SNIP**

If inadequate exposure has been afforded by the medial parapatellar arthrotomy and a complete intra-articular release, a quadriceps snip often provides enough additional exposure to complete the procedure safely.

The snip is made at the apex of the arthrotomy, obliquely across the quadriceps tendon at a 45-degree angle in line with the fibers of the vastus lateralis (TECH FIG 2).

At the end of the procedure, the snip is closed side-to-side using nonabsorbable suture.

The postoperative therapy protocol is not altered if a quadriceps snip has been performed.
COMPONENT REMOVAL

- The femoral and tibial components are then carefully removed as described in Chapter AR-26.
- The patella then is assessed. Its thickness is determined (TECH FIG 3), and if the composite is considered to be too thick (i.e., >25 mm for women and >30 mm for men) or in an otherwise suboptimal position (e.g., lateralized), the component is removed.
- If the component is to be retained, any osteophytes or unresurfaced sections of the native patella are removed.

RECUTTING THE UPPER END OF THE TIBIA AND PERFORMING A POSTERIOR RELEASE

- The proximal tibia is recut perpendicular to its mechanical axis with neutral slope. Either an intra- or extramedullary guide may be used. A neutral slope is recommended, so rotation of the cut is not important at this point. The revision component often has an appropriate amount of slope built in (5–7 degrees) so that rotation in the optimal position can be set later.
- A laminar spreader then is inserted both medially and laterally, and the scar tissue in the posterior aspect of the knee along with any remnant of the posterior cruciate ligament, if present, is removed completely to re-establish the flexion space and restore full extension (TECH FIG 4A).
- At this point, ligamentous balance is assessed and appropriate releases are performed until the flexion gap is of equivalent size medially and laterally.
- A curved osteotome then is used to release any remaining capsule from the posterior aspect of the femur and to clear any residual osteophytes retained at the time of the original TKA (TECH FIG 4B).
- Given the tendency to elevate the joint line in revision TKA, a complete posterior capsular release is performed in all cases.
CREATING THE TIBIAL PLATFORM

- The tibia is prepared first, because tibial height affects both the flexion and extension gaps.
- The tibial component is then sized to maximize coverage of the upper end of the tibia.
- A stem typically is used to provide support for the revision component. Stems also assist with component alignment. It is necessary to remember that the tibial shaft is offset posteromedially in relation to the center of the upper end of the tibia, and a stem that allows for offset often is required to optimize coverage of the upper end of the tibia (the stem is used to bring the component anterior and lateral in most cases).
- The tibial trial component is then placed in the appropriate amount of external rotation; typically, the center of the component is aligned with the junction of the medial and middle thirds of the tibial tubercle (TECH FIG 5).
- See Chapters AR-23 and AR-25 for additional details.

CHOOSING THE FEMORAL TRIAL SIZE AND AUGMENTS

- Sizing of the femoral component can be difficult but is a critical portion of the procedure. If the original component is thought to have been too large, a smaller trial component is selected.
- The surgeon must keep in mind that, although it is desirable to leave the patient’s knee “somewhat loose in flexion” in cases of stiffness, this does risk flexion instability. Consideration should be given to using a more constrained insert in cases of revision TKA for stiffness.
Chapter 29  REVISION TKA TO CORRECT STIFFNESS

The knee initially is trialed with a long intramedullary stem to assist with determining appropriate valgus alignment; a shorter stem can be substituted later if desired. Stems are used routinely, both to support the revision component and to assist with alignment.

The initial augments typically used include a small posterolateral augment, to encourage appropriate external rotation of the revision component, and small distal augments placed both medially and laterally, to distalize the femoral component in response to the tendency of revision TKA to elevate the joint line.

Appropriate external rotation of the femoral component is checked using the epicondylar axis of the femur (TECH FIG 6A). The surgeon also can check to make sure that a “piano” or “boot” sign is present when the cut surface of the femur is viewed from above (TECH FIG 6B). This sign indicates that the cut on the lateral side is deeper than that on the medial side, confirming appropriate external rotation of the femoral cut.

**TECH FIG 6**  •  A. The epicondylar axis is used to ensure appropriate external rotation of the femur. B. View of the distal femur from above showing the “piano” or “boot” sign, confirming appropriate external rotation of the femoral component.

**TRIALING AND CLOSURE**

The knee is now trialed with varying thicknesses of polyethylene liners to ensure:

- Full extension of the knee (TECH FIG 7A)
- Adequate flexion of the knee (TECH FIG 7B). A good predictor of postoperative flexion is that achieved at the time of surgery with the knee flexed against gravity.
- Adequate varus-valgus stability
- Good patellar tracking. If patellar tracking is not acceptable, the rotation of the femoral and tibial components must be carefully assessed and changed if necessary until the patella tracks well.
- Restoration of the joint line to within 1 cm of its normal position. The easiest way to assess the joint line is to compare the superior pole of the patella to the superior flange of the revision femoral component.

Various combinations of augments and polyethylene liners should be tried until the optimal combination is found; this may take a considerable amount of time to achieve.

The revision components are now assembled on the field. The stems can be either firmly press-fit into the canal, with cement placed only around the metaphyseal segment of the component (see TECH FIG 4C), or fully cemented, depending on the surgeon’s preference. Antibiotic-loaded cement is recommended, given the higher risk of infection in the setting of revision TKA.

The knee is closed in at least 90 degrees of flexion, because this has been shown to increase final flexion. Following closure of the arthrotomy, ROM and patellar tracking are carefully assessed once again.
**PEARLS AND PITFALLS**

| Indications                                                                 | ■ Patients must be assessed carefully before surgery and must have realistic expectations from the procedure.  
| ■ Patients must be willing to be active participants in their postoperative therapy. |
| Pain management                                                            | ■ The assistance of a specialist in pain management is essential to ensure that patients can participate in their physical therapy.  
| ■ An indwelling epidural catheter is a useful adjunct to this goal. |
| Preoperative planning                                                      | ■ Ensure that operative notes from previous procedures have been reviewed and that replacement parts and trials are available if necessary. |
| Perioperative evaluation for sepsis                                         | ■ All patients should have a thorough perioperative evaluation for deep infection. |
| Retention of components                                                    | ■ An arthroscopic or open arthrolysis should be attempted only after the surgeon is sure that the components are well fixed, appropriately sized, and aligned.  
| ■ If not, a full revision should be performed. |
| Patellar tendon avulsion                                                   | ■ Great care should be taken to protect the insertion of the patellar tendon at the time of surgery.  
| ■ More extensile approaches, such as the quadriceps snip or tibial tubercle osteotomy, should be used if deemed necessary. |

**POSTOPERATIVE CARE**

- Perioperative care must be monitored closely in conjunction with a pain management specialist and a physical therapist.
- Patients are placed on a continuous passive motion (CPM) machine starting at 0 to 90 degrees in the recovery room, with the setting advanced as tolerated. CPM is used for 4 to 6 hours per day, and patients must understand that it is an adjunct to, not a substitute for, active and passive ROM exercises.
- The indwelling epidural catheter is continued for up to 6 weeks. The patient is seen by the surgeon and the pain management specialist weekly for the first 6 weeks to monitor progress.
- Patients are engaged in an aggressive physical therapy program emphasizing ROM, gait training, and strengthening.
- If the patient has not achieved 90 degrees of flexion by 6 weeks, MUA is performed.

**OUTCOMES**

- Include functional and prosthetic survivorship data, as applicable.
- Table 1 summarizes the results of arthroscopic release with manipulation, open arthrolysis, and revision TKA for the treatment of stiffness.
- Most of the literature suggests that reoperations for stiffness are associated with improvements in ROM, pain, and function, but that these gains are modest and in a certain percentage of patients, stiffness will recur.
- An arthroscopic release seems most appropriate for select patients with well-fixed, appropriately positioned and rotated components.
- Flexion contractures are particularly difficult to correct.
Chapter 29 REVISION TKA TO CORRECT STIFFNESS

COMPLICATIONS

- Recurrent stiffness
- Extensor mechanism disruption (particularly patellar tendon avulsion)
- Infection
- Instability
- Neurovascular injury
- Deep venous thrombosis

Table 1 Results of Arthroscopic Release with Manipulation, Open Arthrolysis, and Revision TKA for the Treatment of Stiffness
DEFINITION
- Knee arthrodesis is an excellent salvage option for infected total knee arthroplasty (TKA) and for severe trauma about the knee. It is a durable solution that lasts a lifetime and allows for a stable, painless extremity for ambulation.
- The energy expenditure for walking with a knee fusion is less than the energy expenditure needed to walk with an above-the-knee amputation. This is important for elderly patients with associated comorbidities who often are unable to walk with such an amputation.9
- In the younger, posttraumatic population, the knee fusion is a durable option that allows for the most physically demanding activities as opposed to above-the-knee amputation or TKA.
- Ipsilateral hip arthritis or significant back pain and arthritis are relative contraindications to knee fusion, although for some patients, knee fusion is the best option despite relative contraindications.

ANATOMY
- The approach for knee arthrodesis is anterior.
- The relevant anatomy depends on the previous surgical procedures that the patient has undergone. In the case of the infected TKA, the extensor mechanism often is no longer present and a soft tissue defect occurs anteriorly.
- The best bone contact for knee arthrodesis is achieved by elevating the posterior capsule off the distal femur and proximal tibia.
- Directly posterior to the posterior capsule are the popliteal artery, popliteal vein, and sciatic nerve as it branches into the posterior tibial and peroneal nerve. Great care must be taken in the area of these vessels (FIG 1).
- When using a long intramedullary rod for knee fusion, the piriformis fossa is an important landmark for the entry of the nail.
- At present, trochanteric-starting intramedullary knee fusion rods are not available.

PATHOGENESIS
- The conditions necessitating knee arthrodesis include infected TKA and severe trauma about the knee destroying the joint.
- Trauma, destruction, or débridement as a result of infection leads to extensive bone loss.
- The most common way to fill this bone defect is by acutely shortening the limb.
- The average shortening associated with knee arthrodesis after infected TKA is 4 cm, which necessitates a shoe lift to equalize the limb lengths.8
- In cases with substantial bone loss (7 to 10 cm) and with soft tissues and vessels that do not allow acute compression, gradual compression of 2 mm/day with an external fixator is an option for knee arthrodesis, although this still leaves the limb significantly shortened.
- My preference in such situations is for bone transport—either double or single level—in which the overall length of the limb is maintained and the large bone gap at the knee is filled with the transported bone. This strategy works well in the young, traumatized patient and in the elderly patient with infected TKA.

NATURAL HISTORY
- The natural history of these severe traumatic and infectious processes occurring about the knee is poor. Without a stable lower limb, the patients are unable to bear weight.
- The alternative to knee fusion is above-the-knee amputation, which allows the young, healthy posttraumatic population to walk with an above-the-knee prosthesis.
- Above-the-knee amputation in the elderly population with infected TKA usually results in the patient’s becoming nonambulatory.9
- The natural history of a knee arthrodesis is extremely durable, lasting the patient’s lifetime.3
- As the patient ages, however, contralateral hip arthritis (secondary to the longer length of the contralateral limb) and arthritis of the spine (secondary to the increased motion across the spine) can develop. These problems can be addressed separately, if and when they occur.

FIG 1 • Proximity of the posterior neurovascular bundle to the posterior aspects of the femur and tibia at the level of the residual knee joint. Also, the bones are very subcutaneous anteriorly and do not have good blood supply secondary to the relatively avascular quadriceps and patellar tendons and lack of good muscle with good blood flow to the bones anteriorly.
PATIENT HISTORY AND PHYSICAL FINDINGS

The history pertinent to preoperative assessment for knee arthrodesis is a list of all surgical and traumatic occurrences about the knee.

- This includes previous flap surgeries for coverage of the anterior knee and integrity of the extensor mechanism.
- Other important issues regarding the history include comorbidities, such as peripheral vascular disease, smoking, diabetes, ambulatory status, social resources, and steroid use.
  - These comorbidities will affect the patient’s ability to heal a fusion.
  - The surgeon’s choice of technique should take into account these comorbidities to maximize the patient’s chance for a successful outcome.
- Physical examination of the hips and ankles is important to assess the integrity of the remaining joints that will be compensating for the resultant lack of knee motion.
  - Any equinus contracture can easily be addressed at the time of surgery with Achilles tendon lengthening or gastrosoleus recession.
  - The examiner should palpate the dorsalis pedis and posterior tibialis pulses. If they are poor, a vascular evaluation is obtained.
  - The skin of the anterior knee is assessed for scars, previous flaps, defects, and integrity. If the skin condition is poor, the surgeon should consider alternative wound-closure techniques postoperatively, such as a wound vacuum or preoperative plastic surgical consultation.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- The most important imaging studies are long standing anteroposterior (AP) view erect lower limbs radiographs and long lateral view radiographs (FIG 2).
  - These radiographs allow the surgeon to assess the present and predicted limb-length discrepancy after knee fusion.
  - With defects in the knee region greater than 5 or 6 cm, acute compression intraoperatively might lead to vascular compromise from vessel kinking. Therefore, these radiographs are essential for determining the method of fusion.
  - Any residual bone cement in the medullary canals can also be visualized on these views, allowing the surgeon to plan for the proper tools to remove it at the time of surgery.
- Magnetic resonance imaging can be helpful in determining the extent of any infection in the distal femur or proximal tibia. Care must be taken with interpreting the images, however, because bone edema can be misinterpreted as osteomyelitis and result in too aggressive a resection.

DIFFERENTIAL DIAGNOSIS

- Indications for knee fusion:
  - Infected revision TKA
  - Severe trauma about the knee preventing reconstruction
  - Reconstruction after tumor resection

NONOPERATIVE MANAGEMENT

- Nonoperative management of a knee with a significant bone defect after trauma or joint infection is very difficult. These patients typically have an unstable limb for weight bearing and need a cast or brace for support.
- This resection arthroplasty option usually is reserved for nonambulators and patients who are too medically ill to undergo a substantial surgical procedure that involves significant blood loss.

SURGICAL MANAGEMENT

- Surgical intervention is the most effective way to obtain a knee arthrodesis.
  - It requires a patient who is medically stable enough to undergo a 2- to 3-hour procedure with 500 to 800 mL of blood loss.²
Preoperative Planning

- Proper preoperative planning begins with the critical points outlined in the Patient History and Physical Findings and Imaging and Other Diagnostic Studies sections.
- Essential to preoperative planning is determination of the resultant gap that will be present at the site of the knee fusion (Table 1).
- Acute compression of the gap with intramedullary rod fusion should be reserved for gaps no more than 5 to 6 cm. Acute compression greater than that can cause vessel kinking and ischemia to the lower limb.
- Gaps greater than 5 to 6 cm can be managed with gradual compression or bone transport to fill in the defect. Bone transport with a fixator allows the limb to remain at a desired length (1 cm shorter than the contralateral limb) and fills the gap with healthy bone from the proximal tibia or femur.
- In cases with large gaps, gradual compression without lengthening, achieved by using an external fixator, will eliminate vessel kinking, but the resultant limb-length discrepancy might be undesirable for the patient and require him or her to wear a 2- to 3-inch shoe lift, which can be cumbersome for ambulation.
- It is vital to discuss the goals of knee arthrodesis with the patient before surgery. The surgeon must be sure that the patient is willing to accept a large shoe lift; if not, the patient must be willing to undergo additional steps to ensure that the limb is of acceptable length.
- The strategy for knee fusion is patient dependent, and the lengthening can be performed at a second surgical setting or during the same surgical setting. It is important to realize that with concomitant lengthening, the rate-limiting step in the complete healing process is the fusion site, not the regenerate bone formation.
- All knee fusions after infected TKA are bone grafted. This is done when there is no evidence of infection.
- For patients undergoing two-stage procedures (infection eradication and spacer plus clean fusion with intramedullary rod or plates), the bone grafting is performed at the time of the fusion.
- In patients who have external fixation and for whom fusion is initiated at the time of the infection eradication surgery, bone grafting is performed at a second surgical setting.
- Regardless of the method of fusion, fusion after infection requires two surgical procedures.

- My preferred method for obtaining a large volume of bone with minimal donor site morbidity is to use the Reamer-Irrigator-Aspirator System (Synthes, Inc., Paoli, PA). The reamer is used to obtain a large volume of bone from the contralateral femoral canal through a small (2-cm) incision.

Hardware Considerations

Long Knee Arthrodesis Rods

- The long intramedullary rod is an excellent method of fixation for knee arthrodesis. It is well tolerated by patients and provides good neutralization of the forces generated by the muscles around the knee.
- Biomet, Inc.: Biomet Trauma (Warsaw, IN), Smith & Nephew (Memphis, TN), and Stryker Orthopaedics (Mahwah, NJ) are three companies that currently offer long knee fusion rods.
- The Stryker intramedullary rod is the only one with 5 degrees of valgus to counteract the mild varus mechanical axis of the limb with insertion of a straight rod.
- The Stryker rod also has the ability to compress the fusion site after rod insertion and locking.
- This is done by a proximal compression bolt end cap inserted in the proximal rod. The compression bolt end cap sinks into the rod and engages the proximal interlocking screw in the dynamic slot. This allows for an additional 1 cm of compression at the fusion site, which can be helpful after rod insertion.

Short Intramedullary Fusion Rods

- Short intramedullary fusion rods are rods that couple at the knee arthrodesis site.
- The one that is commercially available is called the Wichita Fusion Nail (Stryker).
- The device (FIG 3) has two separate segments of different diameters for the femur and tibia. Each segment is fixed with interlocking screws, and a coupling device is then used to engage and compress the bone ends.
- The device works very well for the primary knee arthrodesis that has good metaphyseal bone.1
- Without good metaphyseal bone and tight-fitting rods in the femoral and tibial canal, the Wichita Fusion Nail does not provide enough stability to neutralize the long lever arms across the knee.
- Preoperative planning is essential to ensure that the tibial and femoral rods will have good fit in the bone. The femoral rod is 14 cm long, and the tibial rod is 16 cm long.
- If the distal femur and proximal tibia appear as “cortical shells” without good bone, another method should be chosen.

External Fixation

- Many systems are available for external fixation, but my preferred method is a biplanar Orthofix LRS external fixator (Verona, Italy; FIG 4).
- This system has two long smooth rails (65 and 80 cm) that are mounted anteriorly and laterally from the hip to the ankle to adequately neutralize the long lever arms across the knee. It also allows for purchase of the bone in an area not violated by any long revision TKA stems.
- The advantages to external fixation are that at the completion of the fusion, no hardware remains as a nidus for recurrent infection and the external fixator can be applied at the same surgical setting as the removal of infected TKA components or débridement of osteomyelitis. This allows for immediate initiation of bone contact and knee fusion.
It is not recommended to perform bone grafting at this setting but to wait until the soft tissue envelope is stable and no fear of infection at the knee fusion site remains. This often is done 6 to 8 weeks after the application of external fixation.

Also, with a circular or biplanar system, external fixation can be set up so that as the fusion is uniting, the resultant limb-length discrepancy can be diminished by performing an osteotomy of the proximal femur or distal tibia at the same surgical setting.

Circular fixation, with the rings sitting at the medial aspect of the thigh, can be cumbersome for large or elderly patients—hence the description of the biplanar Orthofix external fixator.

Any monolateral system can be set up in a biplanar fashion. The system used must span the length of the femur and tibia to achieve rigid fixation.

**Plates**

Plates are not commonly chosen implants for knee fusion because of the bulkiness of the plates and the lack of soft tissue envelope in the anterior aspect of the knee. However, plates might be preferred for patients with total hip arthroplasty above the desired fusion site.

The ideal construct for plates should be a 90-90 construct in which an anterior plate is used to counteract the flexion–extension forces and a medial or lateral plate is used to counteract the varus–valgus forces.

The plates should initially be used in compression mode, and the remaining screw holes should be inserted in a locking fashion into a locked plate.
Many plating systems are commercially available with locking capability (Synthes, Smith & Nephew).

**Positioning**
- The positioning for knee fusion is the same for each surgical approach.
- A bump is placed under the buttock to allow for visualization of the femoral neck and head on the lateral view radiograph.
- The entire limb, including the foot, needs to be visualized to ensure proper rotation of the limb during surgery and also to assess the pulse during the procedure (**FIG 5**).

**Approach**
- The basic approach to knee fusion is anterior.
- Without any soft tissue compromise, the best incision for knee fusion is a transverse one that will be easily approximated once the limb is acutely shortened.
- A longitudinal incision becomes difficult to close once the bone ends are shortened (**FIG 6A,B**).
- The transverse incision allows for removal of a TKA without difficulty.
- If knee fusion is performed as a solution for infection (post-traumatic or infected TKA), the fusion often can be initiated at the same surgical setting as the débridement.
- The preferred technique is to use a Mayo stand for the débridement (**FIG 6C**).
- The scrub technician places the required instruments onto the Mayo stand, and the surgeon retrieves them as needed. When débridement is completed, the “dirty” Mayo stand is moved away and the limb is reprepared, additional clean drapes are placed, and new gowns are used.
- New Bovie, suction, and light handles are used for the clean procedure.
- A high-speed burr with continuous cooling irrigation is used for débridement of clean, healthy, bleeding bone and to obtain good bone surfaces for maximum bone contact during compression.
- A Versajet hydroscalpel (Smith & Nephew) is used to achieve thorough débridement of the soft tissue and especially the posterior capsule. Use of the Versajet is a very safe way to achieve maximum soft tissue débridement.
- The back of the capsule is always freed from the posterior aspect of the bone to allow good bone contact without compromising the vessels behind the capsule. This usually is done very carefully with the Cobb.
- Once the bone ends are prepared, any of the methods described below can be used to stabilize the fusion.

**FIG 5** - Intraoperative patient positioning used for all knee fusion cases. The entire limb is prepared, with a bump under the ipsilateral buttock. The bump allows for access to the proximal femur for intramedullary rodding or placement of external fixator pins.

**FIG 6** - Transverse anterior knee incision during the surgical procedure (**A**) and postoperatively (**B**). Note the excellent exposure and the excellent wound healing postoperatively. **C.** A separate Mayo stand is used only for the “dirty” or débridement portion of the surgical procedure.
LONG INTRAMEDULLARY ROD INSERTION

Incision and Exposure

- This technique begins with a transverse incision at the knee, centered between the tibia and the femur as determined using fluoroscopy.
- A transverse incision is designed to heal when the bone ends are compressed.
- After the initial exposure, cutting transversely through any remaining patellar tendon or quadriceps tendon, the bone ends are exposed.
- All soft tissue that is tethering the bone ends’ ability to compress must be released without jeopardizing the blood supply to the fusion site.
  - This includes, as mentioned above, freeing the capsule from the posterior aspects of the femur and tibia in a very careful fashion with the Cobb to get direct contact of the bone ends.
- Bone is resected in a careful fashion to minimize the resultant shortening of the limb and to achieve the maximum bone contact possible. Any necrotic bone must be resected.

Reaming the Tibia and Femur

- Once the bone ends are prepared, the tibia is reamed first.
- The femur must be reamed to the same diameter that the tibia was reamed so that maximum stability of the fusion can be achieved with the nail.
  - Overreaming the femur will disallow the best tight fit of the nail into the femoral canal.
  - This is secondary to the fact that the nail diameter is the same from the proximal femur to the distal tibia.
- Previous knee fusion rods had different diameters for the femur and tibia but are no longer commercially available. If this type of rod were available, the femur would be reamed to 1 mm more than the available diameter for the femur (TECH FIG 1).
- The tibia and femur are reamed separately over a guide rod.
  - The tibia is reamed in an antegrade fashion, whereas the femur is reamed in a retrograde fashion.
  - The guide rod is tapped out of the proximal femur through the piriformis fossa. This is an extremely easy way to find the nail insertion site at the proximal femur.
  - Care must be taken, however, to ensure that this does not place the starting point too medial. If this seems to be the case, the proximal starting point is found with a Steinmann pin proximally to ensure that the dreaded complication of femoral neck fracture will not occur from too medial a starting point.

Inserting the Rod

- Rod insertion is the most important part of the case in two respects.
  - The first is to ensure that the bone ends are lined up and there is compression at the fusion site with insertion. It is critical that the bone ends are lined up evenly with the guide rod inserted the entire distance from the femur to the ankle because the rod can still deviate in the soft bone with insertion and violate the cortical wall. Holding the bone ends compressed will also ensure maximum contact at the fusion site after the nail is completely inserted.
  - Second, ensuring the proper rotational alignment of the limb at this stage is critical. The initial position of the limb when prepared was on a bump to internally rotate the limb. When inserting the rod, the limb is adducted. Because of the internal rotation from the bump, my final position for the foot once the limb is adducted is perpendicular to the floor. This ensures some external rotation of the limb once the bump is removed (TECH FIG 2).
Do not count on fixing rotation once the nail has engaged the tibia. Because of the tight fit of the nail in the tibial canal and the anterior bow of 5 to 7 degrees—and, if a Stryker knee arthrodesis rod is used, an additional 5 degrees of valgus that is in the nail—rotating the tibia once the rod is fully engaged in the tibia can lead to tibial fracture.

Once the rod is inserted and locked proximally with a guide arm, additional compression can be achieved at the knee fusion site by holding the foot and driving the rod in more with three or four more mallet slaps to the insertion handle.

The limb is then taken out of adduction and locked distally with the use of a fluoroscopy-guided “perfect circle” freehand technique.

Make sure that adequate compression is maintained until the locking screws are inserted.

The Stryker knee arthrodesis rod has the added feature of a compression screw that can be inserted proximally and allows up to 1 cm of additional compression after the distal interlocking screws are inserted.

**Wound Closure**

- After nail insertion, the incisions are closed with absorbable monofilament suture.
- If nail insertion was performed in a clean fashion, bone graft, bone morphogenic protein, or both can be added to the fusion site before closure. This is especially helpful if minor gapping is present at the fusion site.

**SHORT INTRAMEDULLARY ROD INSERTION**

- The surgical approach can be a standard medial parapatellar approach or through the transverse incision mentioned above.
- Once the bone ends are exposed, an intramedullary guide is used to align the distal femoral and proximal tibial cuts in about 5 degrees of flexion and neutral varus-valgus alignment.
- A trial reduction of the bone ends is performed after the bone cuts to check the bone apposition and alignment. Great care should be taken to obtain good bone contact at the fusion site.
- Another factor to keep in mind is the resultant limb shortening. The average knee arthrodesis is 4 cm short. Too aggressive a resection will result in more shortening and the patient will need to wear a large, bulky, and awkward shoe lift.
- Another way to ensure some flexion in the system is to ream the femur from distal-posterior to proximal-anterior. Because the tibial canal is smaller, it is more difficult to ream the tibia in an eccentric fashion like the femur.
- Once the femur is reamed, the femoral rod is inserted and locked with the targeting arm. Two screws are placed in a lateral-to-medial fashion.
- A slot is then cut into the tibia to allow for the coupling mechanism between the two rods and the tibial guide arm for the interlocking screws.
- The bone plug is saved for grafting at the end of the case.
- There are two options for the tibial screws. Use the ones that will capture the best bone.
- The tibia is then inserted and locked in a medial-to-lateral fashion.
- When inserting the screws, placing a bump underneath the knee will ensure that the femur and tibia are locked with the rods in some flexion, ideally 5 degrees.
- Once the rods are placed and locked, an additional femoral slot can be removed to allow further visualization of the coupling mechanism. This bone plug is also saved for grafting at the end of the case.
- Make sure that the rotational alignment is in neutral to 5 degrees external before completely engaging the tibial rod in the femoral rod and screwing down the compression mechanism. Tighten the screw to get good compression at the bone ends. Take care not to overtighten, or the bone ends might fracture.
- Once the fusion site is compressed, the bone plugs are replaced as bone graft and the incision is closed.
- Full weight bearing is allowed after this procedure if the surgeon is satisfied with the amount of bone contact at the fusion site.

**EXTERNAL FIXATION**

**Application of the Lateral Rail**

- The first step after adequate exposure of the bone ends and débridement of any residual infection is the application of the lateral rail.
- The lateral rail is set up with four clamps: two for the tibia and two for the femur.
- The most proximal clamp is placed at the level of the lesser trochanter, perpendicular to the femoral shaft on the AP view and in the midshaft of the femur.

- It is very important when placing the proximal femoral pins to ensure that they are not positioned too anteriorly in the femoral shaft. This is a major stress riser and can cause a femoral fracture.
- Once one proximal pin is inserted, the most distal tibial pin is then inserted perpendicular to the shaft of the tibia in the AP view.
- Rotation of the limb is set with this pin insertion.
- I prefer to have the toes perpendicular to the floor because when the proximal bump is removed from...
under the buttock, the foot will be about 10 degrees externally rotated.

- After the pin insertions, the middle clamps are positioned (TECH FIG 3).
  - Positioning of the clamps is variable and based on the bone quality at the proximal tibia and distal femur.
  - Ideally, the greater the span of the clamps, the better fixation of the bone.
- A lateral view radiograph is obtained to check the middle clamps.
  - The clamps often are too posterior to hit the bone and need to be moved proximally or distally accordingly.
  - The clamps can also be adjusted by adding a half or full “sandwich” to the clamps to raise the pin insertion site more anteriorly. It is preferable to use the sandwiches to raise the pin insertion sites as opposed to moving the clamps further away from the knee joint.
  - It is at this stage that the flexion of the knee can be “set” into the system.
  - More flexion will necessitate raising the middle lateral two clamps more anteriorly to hit the bone.
  - My usual position is 5 degrees of flexion. This minimizes any additional limb shortening from excessive flexion.
  - In this position, the two middle clamps need one full sandwich to hit the bone.
  - After the insertion of one pin in each clamp, the remaining pins are inserted for a total of eight half-pins (two pins per clamp).
  - The preferred half-pins are hydroxyapatite-coated and are inserted so that the thread distance is the same as the diameter of the bone.

- If the threads remain outside the bone, the pin is weaker than if the threads were buried to the shank.

### Checking Alignment and Mechanical Axis

- Once all the pins are inserted, a Bovie cord is used to check the mechanical axis of the limb. The limb is first placed in the “patella forward” position. Under fluoroscopic guidance, the Bovie cord is used as a straight line from the center of the femoral head to the center of the ankle. After confirming these points, fluoroscopy is used to check where this line or mechanical axis lies at the knee. It should be in the center of the knee or slightly medial. If it is not, the tibial pins can be translated in the clamps more medial or more lateral until the mechanical axis is acceptable.
  - Once this is the case, the pins are secured in the clamps and the tibial clamps are linked with a compression–distraction device. The proximal femoral clamps are secured to the rails.
  - A second compression–distraction device is then placed between the tibial and femoral clamps and compressed.
  - The knee fusion site is visualized during the compression to ensure good bone contact and to make sure there is no soft tissue interposition at the bone ends.

### Wound Closure

- Once the bone ends are opposed and compressed, the anterior knee wound is closed, usually over a drain.
- Once the lateral rail is applied and the wound is closed, it is very easy to apply the anterior fixator. The long rail is placed anteriorly with four clamps set up in the same
fashion as the lateral rail. The clamps are placed so as not to hit the other pins upon insertion of the anterior pins (TECH FIG 4).

- Additional compression can be obtained at the knee fusion site in the office by using the compression-distraction device between the femoral and tibial clamps.

**TECH FIG 4** • The mounted Orthofix LRS after the lateral fixator is applied.

---

**PLATING**

**Plate Size**

- The number of holes in the plates chosen depends on the bone available for fusion in the tibia and femur.
  - If a total hip arthroplasty is present, stopping the plate immediately distal to this can be a stress riser. In such cases, sliding the plate a few holes past the total hip arthroplasty stem and using unicortical screws in the region is helpful.
- The ideal number of holes is 11: 5 for femoral fixation, 4 for tibial fixation, and 2 left empty at the fusion site.

**Exposure**

- The surgical technique begins with the same exposure as previously mentioned.
- A transverse incision can be used, and the plates can be inserted percutaneously in both the anterior and mediolateral plane.
- Fluoroscopy is used to ensure that the plates are flush and securely fastened to the bone.
- The important step is preparation of the bone ends and good bone contact.
- When using plates, the area must first be “sterilized” with the two-stage approach of using an antibiotic-coated cement spacer and then 6 weeks of antibiotics.
- Once this stage is completed, the plates are inserted as a “clean procedure.” This allows autogenous bone graft to be inserted at the fusion site with bone morphogenic protein.
- After preparation of the bone, the alignment is assessed using the Bovie cord test.
- A four-pin temporary lateral fixator can be helpful to achieve alignment and to hold the alignment while the anterior plate is applied. A good assistant can be as helpful as a temporary fixator.
- Once the alignment is good and the plate is applied with the provisional pins, the next pins to be inserted are close to the fusion site—one on the femoral side and one on the tibial side—placed in compression mode.
  - This does two things: compresses the fusion site and pulls the plate down to the bone.
- Once the two screws are inserted, the remaining screws can be placed in a locked mode.
  - This allows for maximum rigidity of the construct so that some weight bearing can be initiated immediately postoperatively.

**Medial or Lateral Plate**

- After anterior plate insertion, the medial or lateral plate can be applied. This is the easier of the two plates to be inserted because the alignment is now rigid.
- Medial or lateral is best determined by the amount of soft tissue coverage, with the plate being applied where there is the best chance for the best soft tissue envelope.
- Occasionally, a posterior plate can be applied on the lateral side of the knee when the anterior soft tissue is too deficient to cover the plate (TECH FIG 5).
  - This requires repositioning the patient in a prone position to apply the plate.

**Anterior Plate**

- When good bone contact and good alignment are achieved, the plates are applied. The anterior plate is easier to apply first.
- The first step is ensuring that the proximal and distal ends will be well approximated to the bone. This is done with a provisional fixation pin at both ends.
  - Great care must be taken to ensure that the rotational, sagittal, and coronal alignments are maintained while the plate is applied.

**TECH FIG 5** • The mounted Orthofix LRS with the completed frame.
For bone loss of more than 5 cm and noncompressible soft tissue defects at the knee secondary to extensive scarring, bone transport is the best option to fill the defect.

The technique begins with determining the extent of the gap. If the gap at the knee will be more than 10 cm, a double-level transport can be performed.

The first step for transport over a nail is to insert the long intramedullary rod as described earlier.

When inserting the rod, make sure that the limb does not inadvertently lose any length. This can best be accomplished by determining the rod length to be used preoperatively from an erect lower limbs radiograph. The length of the normal side can be used as a reference as long as significant shortening of the affected limb is not also present. The affected limb cannot be acutely lengthened because the soft tissues about the knee are not compliant.

Ideally, the affected limb should be 1 cm short to allow clearance of the foot when ambulating. The average knee fusion shortening is 4 cm, and anything up to this amount is tolerable. Any limb shortening more than this can be addressed with the lengthening over a nail technique at the completion of the transport.

The rod diameter chosen for the transport is 10 mm. This allows the transport segment to slide over the rod when the canal is reamed to 12 mm.

Determine the segment to be transported.

The femur is the preferred segment because of the need to perform only one osteotomy and because of the detrimental effects that proximal tibial transport can have on the ankle (equinus).

If, because of the large segmental defect, tibial transport proximally is necessary, the fibula should also be osteotomized at the midshaft and a distal syndesmotic screw should be placed to prevent any proximal fibular migration.

Mark out the osteotomy site of the transported segment.

Once the guide rod is inserted into the femur and tibia, the rod is backed out past the level of the osteotomy and the osteotomy is predrilled with multiple drill holes before reaming.

This allows the reamings to exit out the osteotomy site and to “bone graft” the regenerate site.

The first step is reaming the intramedullary canal of the tibia and femur to 12 mm.

This can be done through the knee, reaming the tibia and femur separately, or from the hip using long 80-cm reamers (Biomet Trauma, Stryker).

Once the rod is inserted and locked at the desired length, the monolateral external fixator is applied.

Applying the monolateral frame to move the transported segment over the nail requires inserting the pins so that there is no contact between the rod and the pins.

With this technique, because the rod and pins are so close, there is a 5% chance for infection of the rod.6

My preference for the femur is to use a lateral Orthofix LRS frame with two pin clamps. Three half-pins are inserted into the proximal clamp, and three half-pins are inserted into the distal clamp. The pins are inserted by using a cannulated wire technique.

The cannulated wire technique starts with a 1.8-mm wire inserted perpendicular to the rod on the AP view fluoroscopic projection but away from the rod by a few millimeters on the lateral view projection.

The most common location in the femur for these pins is proximally and posteriorly at the level of the lesser trochanter (TECH FIG 6).

Once the wire is inserted, it is confirmed using fluoroscopy. The fluoroscopic view must show the wire “on end.”

This is to confirm that when the pin is drilled and placed, it will not be touching the rod. This technique can be very time-consuming.

Fluoroscopy must be used frequently to confirm that the pins are placed away from the rod.

**TECH FIG 6**  • Steps involved in the transport over a nail technique. Bone graft and a plate are applied to the docking site and the fixator is removed at the final surgical setting.
Once the wire is in a satisfactory position on the AP and lateral view projections, a 4.8-mm cannulated drill bit is used to drill the near cortex. This drill bit and the wire are then removed, and a solid 4.8-mm drill bit is used to complete the tract for the pin.

- Drilling with the cannulated drill bit and then the solid drill bit is important because the cannulated drill bit is not end-cutting and sharp enough to go through the cortical bone of the far cortex. Often, these pins are placed entirely in the cortical bone.

- When using the drill, it is imperative that the drill bit not heat up and cause osteonecrosis of the bone.

- If this happens, the pin will become infected and aseptic bone sequestrum will develop. Also, an infected pin places the intramedullary rod at risk for contamination.

- To prevent this, the drill bit is removed at regular intervals while drilling to be cooled and cleaned with a wet, cool laparotomy sponge.

- Once the bone is drilled, a 6-mm hydroxyapatite-coated pin is inserted.

- After insertion of the pins with use of the Orthofix clamp as a guide, the frame is removed and the bone is cut with an osteotome.

- A small incision is used laterally at the level of the femur.

- Often, the bone cannot be completely cut through one incision around the rod. A second incision is then placed anteriorly to complete the osteotomy along the medial femur.

- If the tibia is chosen, the incisions are placed anteriorly and medially to obtain access to the lateral cortex and posteromedial cortex, respectively.

- Once the bone is cut, the pins are used to carefully rotate the bone and determine that the osteotomy is complete.

- When the osteotomy is complete, the fixator is reapplied and the osteotomy site is distracted to ensure that the bone ends will separate.

- This is confirmed by using fluoroscopy, and the osteotomy site is then reapproximated.

- This completes the procedure after the wound closures and dressings.

- Postoperatively, the pins are cleaned daily with saline and redressed with a Kerlix dressing wrapped tightly around each set of pins.

- The dressing prevents skin pistoning around the pins and limits the soft tissue trauma that leads to pin tract infections.

- Touch-down weight bearing for balance only is permitted postoperatively.

- Full weight bearing is permitted once two cortices are present at the regenerate site on the radiographs, once the consolidation phase of bone healing has begun.

- Distraction is begun at postoperative day 5 and is continued until the gap is closed at the knee region.

- When the gap has closed, the patient is brought back to the operating room for insertion of bone graft at the docking site and percutaneous locked plating at the docking site. The locked plating is essential to prevent the transported bone end from migrating.

- Custom rods with predrilled holes to lock the transported segment significantly weaken the rod and are not recommended.

- Once the bone graft and locked plate are inserted, the external fixator is removed.

- If the limb is still significantly short after the docking of the transported segment, the distal interlocking screws are removed from the rod and the external fixator is left in place to continue lengthening.

- Once the desired length is achieved, the patient is returned to the operating room for the insertion of the locking screws and removal of the external fixator.

- The patient is allowed full weight bearing once two of the four cortices are present on the radiographs.

### PEARLS AND PITFALLS

**Poor bone approximation on one side of the fusion or anteriorly**

- This is common anteriorly with good approximation of the medial, lateral, and posterior bone ends. As long as 50% of the diameter of the bone is approximated at the time of fusion, with those bone ends being viable and healthy, the fusion will be successful. Secondary bone grafting can be performed at the defect site. More bone contact is preferred, but not at the expense of massive limb-length discrepancy. If massive limb-length discrepancy is to occur, a different strategy for fusion should be used.

**Difficulty holding the position of the knee fusion with rod insertion**

- Temporary use of an external fixator (one or two pins proximally and one or two pins distally) with the pins placed out of the path of the nail will hold the fusion in a compressed and properly rotated position when inserting the rod. This application is very helpful but not frequently needed for the straightforward fusion.

**Femoral neck fracture**

- Too medial a starting point for the insertion of the antegrade long knee fusion rod can result in a femoral neck fracture. This is very difficult to treat and is best treated with exchange rodding to a long custom knee fusion cephalomedullary nail with screws into the femoral neck and head.

### POSTOPERATIVE CARE

- Postoperatively, regardless of the technique, the patient is encouraged to strengthen the hip and ankle.

- For patients with external fixators, pin tract infections are likely to occur and are initially treated with orally administered antibiotics.

- All patients are given a prescription for an antibiotic to be taken orally, most commonly cephalixin, before discharge and are instructed to start the antibiotic at the first sign of redness, increased tenderness at the pin site, or drainage.

- Follow-up office visits are every 2 weeks for patients who are undergoing bone transport or lengthening. Once the
consolidation phase starts, only monthly follow-up visits are required.
- For patients with external fixation, once the bone has consolidated, the frame is then dynamized in the office 1 month before removal.
  - Dynamization of the frame usually is performed by taking the tension off the compression–distraction devices. This allows the bone to accommodate more load and become stronger before the frame is completely removed.
  - If the bone is strong enough, no pain should occur with dynamization in the office setting.
- For patients with external fixation, if bone graft was not performed at the time of fusion, a second-stage bone grafting procedure can be performed once there is no longer any evidence of infection, approximately 6 to 8 weeks after the index procedure.
- Most patients will need shoe lifts added to the outside of the shoe during the postoperative period.

OUTCOMES
- Harris et al\(^5\) compared the function of knee arthrodesis with that of constrained TKA and found that the knee arthrodesis patients had better stability and performed more physically demanding activities.
- Rud and Jensen\(^11\) examined 23 knee arthrodesis patients and found that 18 had returned to work.
- Most patients should expect to have difficulty with stairs, rugs, and ladders,\(^12\) and patients who performed strenuous work before the arthrodesis rarely resume that strenuous work postoperatively.
- Rand et al\(^10\) reported that seven patients with knee arthrodeses could walk one to three blocks and nine successful knee arthrodesis patients were able to walk more than six blocks.
- Compared with the alternative—above-the-knee amputation—knee fusion offers a stable, painless, and uninjured limb for weight bearing. Most knee arthrodesis patients are ambulators, whereas, according to Pring et al\(^9\), of 23 patients who underwent an above-the-knee amputation for infected TKA, only 7 were ambulators.
- The best way to achieve the best outcomes for these patients with difficult problems is to be thorough in the preoperative discussions regarding what knee arthrodesis can achieve for them.
- Realistic patient expectations are critical in achieving successful outcomes.
- Although revision TKA might be the more attractive alternative, many patients are not proper candidates for that procedure secondary to a poor soft tissue envelope, bone loss, and recurrent infection.
- Hanssen et al\(^4\) documented that 50% of patients with infected revision TKA eventually went on to knee arthrodesis.

COMPLICATIONS
- The complications associated with knee arthrodesis are related to the increased stress placed on the hip, back, and ankle. Osteoarthritis can occur in those areas.
- Takedown of the knee fusion in these circumstances is not recommended, secondary to the extensive complications reported in the literature.\(^7\)
- Other complications that occur include recurrent infection and nonunion.
- These complications can be very difficult to treat, considering the many medical comorbidities in the older population.

DEFINITION
- Forearm shaft fractures represent the third most common fracture encountered in the pediatric population.¹
- Closed fracture care is successful in the large majority of children who sustain forearm shaft fractures (especially the common greenstick fracture pattern).
- For children who are 8 to 10 years of age and older with complete fracture patterns, the limits of acceptable displacement (angulation, rotation, and translation) become more strict and the likelihood of surgical intervention increases.⁵

ANATOMY
- The forearm represents a largely nonsynovial two-bone joint with a high-amplitude range of motion (roughly 180 degrees).
- In the fully supinated anteroposterior (AP) plane the radius bows naturally out and away from the relatively straight ulna, while both bones are predominantly straight in the lateral plane.
- Anatomically the shaft of the radius extends from the most proximal aspect of the tubercle of Lister (which approximates the distal metaphyseal-diaphyseal junction) to the proximal base of the bicipital tuberosity. The shaft of the ulna corresponds to these same points on the radius (FIG 1).⁵,⁶
- In unfractured bones the normal orientation of the radial styloid and bicipital tuberosity is slightly less than 180 degrees from one another, while the ulnar styloid and coronoid process come closer to a true 180-degree relationship.
- Classically, forearm shaft fractures are divided into distal third (pronator quadratus region), central third (pronator teres region), and proximal third (biceps and supinator region). These anatomic relationships offer insight into the deforming forces acting on the fractured forearm (FIG 2).

PATHOGENESIS
- Forearm shaft fractures most commonly occur secondary to a fall on an outstretched arm and usually involve both bones. Forward falls tend to involve a pronated forearm and backward falls a supinated forearm.
- Single-bone forearm shaft fractures should raise significant suspicion regarding the presence of a Galeazzi or Monteggia-type injury (see Chap. PE-52).
- Mechanisms of injury that involve little rotational force result in forearm fractures at nearly the same levels, while greater rotational force results in fractures at rather different levels.

NATURAL HISTORY
- The remodeling potential of the pediatric forearm shaft has been well documented and is considered to be most predictable in children less than about 8 to 10 years of age.
- Spontaneous correction and improvement of malaligned shaft fractures are considered to occur in young children via three mechanisms:
  - Adjacent physis produce “straight bone” via normal growth.
  - Physeal orientation tends to “right its horizon” via the Hueter-Volkmann law.
  - True shaft remodeling occurs via Wolff’s law.⁹

PATIENT HISTORY AND PHYSICAL FINDINGS
- The clinician should gather as much pertinent information as possible regarding the mechanism of injury (eg, a fall from the bottom step of the playground sliding board may be much different from a fall from the top step of the same sliding board).
- The clinician should determine whether the patient has any other complaints of pain beyond the forearm shaft region (eg, wrist or elbow tenderness). Any perceived deformity or pain to palpation should trigger dedicated radiographs of the problematic region.
- The clinician should elicit any past history of fracture or bone disease in the patient or the patient’s family.
- Physical examination of the skin of the child’s forearm should be performed to rule out the presence of an open fracture. Any wound, no matter how small or seemingly superficial, should be carefully evaluated. Persistent bleeding or oozing from a small suspicious wound should be considered an open fracture until proven otherwise.
- The environment of the injury has special significance for open fracture management. For instance, farm-related injuries may alter the treatment regimen for the patient.
- Multiple trauma or high-energy trauma scenarios dictate that a screening orthopaedic examination be performed to help rule out injuries to the other extremities as well as the spine.
- Brachial, radial, and ulnar pulses should be palpated and distal capillary refill should be assessed.
- Sensory examination should include, at minimum, light touch sensation testing (or pin prick testing if necessary) of the autonomous zones of the radial, ulnar, and median nerves. Older children may be able to comply with formal two-point discrimination testing.

![FIG 1](image-url) - The radial diaphysis extends from the most proximal aspect of the tubercle of Lister to the proximal base of the bicipital tuberosity. The ulnar diaphysis corresponds to these same points on the radius.
• It has been said that you need only a thumb to test the motor function of all three major nerves: radial nerve = extensor pollicis longus, ulnar nerve = adductor pollicis, median nerve = opponens pollicis.
• Peripheral nerves in the fractured extremity are assessed with the "rock-paper-scissors" method.
  • The radial nerve (really the posterior interosseous nerve in the forearm) is tested with "paper"—extension of the fingers and wrist well above a zero-degree wrist position. The autonomous zone is the dorsal web space between the thumb and index finger. There is a risk of iatrogenic injury during surgical exposure of the proximal radial shaft.
  • The ulnar nerve is tested with "scissors"—adducted thumb, abducted fingers, and flexor digitorum profundus function to ring and pinky. The autonomous zone is palmar tip pinky finger. This is the most common iatrogenic nerve injury after internal fixation of forearm shaft fractures.
  • The median nerve is tested with "rock." The autonomous zone is palmar tip index finger. The median is the most commonly injured nerve after closed or open forearm shaft fractures.
  • The anterior interosseous nerve is tested with the "okay" sign. Flexion of the distal interphalangeal of the index finger and the interphalangeal of the thumb herald flexor digitorum profundus and flexor pollicis longus function of these digits. This is a motor branch only (it has no cutaneous innervation, only articular). Isolated palsy has been reported secondary to constrictive dressings and after proximal ulna fracture.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

• AP and lateral radiographs (two orthogonal views) that include the entire radius and ulna are essential for proper diagnosis of forearm shaft fractures in children (FIG 3). If suspicion exists for compromise of the distal or proximal radioulnar joints (Galeazzi or Monteggia injuries), dedicated wrist and elbow radiographs are also indicated.
• If fracture angulation is noted on both orthogonal forearm views, the true fracture angulation exceeds that measured on either individual view (FIG 4).
The radiographs should be used to classify the forearm fracture in a practical fashion with respect to “2 bones, 3 levels, 4 fracture patterns” (Table 1). This is akin to describing bone tumors in terms of matrix, margins, and so forth.

**DIFFERENTIAL DIAGNOSIS**

- Galeazzi injury (concomitant distal radioulnar joint disruption)
- Monteggia injury (concomitant proximal radioulnar joint disruption)
- Coexisting distal humeral fracture (eg, supracondylar humeral fracture, also known as floating elbow)
- Open fracture (the clinician must be aware of small, innocuous-appearing wounds)
- Compartment syndrome (more common in setting of floating elbow and extended efforts at indirect reduction of difficult-to-reduce fractures)

**NONOPERATIVE MANAGEMENT**

- Nonoperative (closed) fracture management is used in the vast majority of pediatric forearm shaft fractures.
- Successful nonoperative treatment requires an eclectic mix of anatomic knowledge, skillful application of reduction techniques, appreciation for remodeling potential, and respect for the character of the soft tissue envelope.
- Greenstick fracture patterns retain a degree of inherent stability; intentional completion of these fractures is not recommended. Davis and Green reported a 10% loss of reduction rate with greenstick fractures and a 25% rate with complete fractures.2
- Greenstick fracture patterns often involve variable amounts of rotational deformity such that when the forearm is appropriately derotated, reduction of angulation occurs simultaneously.
- Apex volar greenstick fractures are considered to represent supination injuries that require a relative degree of pronation to effect reduction.
- Apex dorsal greenstick fractures are considered to be pronation injuries that require supination to aid reduction.
- Classic finger-trap and traction reduction techniques are probably best reserved for complete both-bone fracture patterns. When dealing with complete both-bone shaft fractures, respect should be paid to the level of the fractures when choosing a relatively neutral, pronated, or supinated forearm position.
- Price has suggested that estimated rotational malalignment should not exceed 45 degrees.3 The related concepts of maintenance of an appropriate amount of radial bow and interosseous space on the AP radiograph must also not be forgotten, but precise criteria do not exist at this time.
- Initial above-elbow cast immobilization is the rule for all forearm shaft fractures, as this appropriately controls pronation–supination as well as obviating the orthopaedic maxim of immobilizing the joints above and below the fracture. An extra benefit of above-elbow immobilization relates to the activity limitation it imposes; in some instances this may increase the chances of maintaining a satisfactory reduction in an otherwise very active customer.

**SURGICAL MANAGEMENT**

- Flexible intramedullary nail treatment of pediatric forearm shaft fractures focuses predominantly on displaced complete fractures, many of which may have minor comminution (butterfly fragments usually less than 25% of a shaft diameter).
- When efforts at closed fracture management do not achieve and maintain fracture reduction within accepted guidelines, surgical treatment is indicated.
- When complete fractures occur in children younger than about 8 to 10 years of age with angulation of at least 20 degrees in the distal third, 15 degrees in the central third, or 10 degrees in the proximal third, risk–benefit discussions are appropriate regarding further efforts at fracture reduction and possible internal fixation.3,10
- Lesser measured angulation associated with significant forearm deformity (as defined in a discussion between the orthopaedic surgeon and the parents) may also prompt intervention in selected children.
- Complete forearm shaft fractures in children older than 8 to 10 years of age should be evaluated very critically with the intention to accept no more than 10 degrees of angulation at any level.3,10 Compromise (loss) of interosseous space should also be considered, as well as rotational malalignment (difficult to assess precisely) when debating the merits of continued cast treatment versus flexible intramedullary nail fixation.

**Preoperative Planning**

- Rotational alignment of the radius and ulna should be assessed and estimated using the guidelines mentioned in the Anatomy section. Concern is increased if greater than 45 degrees of rotational malalignment is judged to be present.
- Measurement of the narrowest canal diameter of the radius (usually midshaft) and ulna (usually distal third) will aid in the selection of appropriately sized intramedullary nails. Implants 2 mm in diameter or smaller are commonly used, and the same-sized nail is used in each bone. It is far worse to select implants that are too big rather than too small.
- Assessment of existing or impending comminution is prudent. Significant comminution may lead the surgeon to choose plate fixation over intramedullary fixation for one or both bones.
- Assessment of the soft tissue envelope of the forearm is important. Tense swelling of the forearm certainly increases suspicion for compartment syndrome, and the surgeon should be prepared to measure compartment pressures accordingly.
Positioning

- The patient is placed in a supine position on the operating room table with the involved extremity positioned on a sturdy hand table to allow easy, unobstructed radiographic visualization of the entire forearm (FIG 5).
- In general, the monitor for the portable fluoroscopy unit should be positioned near the end of the operating table, opposite the imaging unit (C-arm).
- A nonsterile tourniquet may be applied about the upper arm (near the axilla) before preparation and draping, but it is not routinely inflated.
- The limb is appropriately prepared and draped, with care being taken to ensure that the first layer is a sterile impervious one (eg, blue plastic U-drape). The C-arm is also appropriately protected with a C-arm sterile plastic drape and an additional sterile skirt (usually a sterile paper half-sheet). Without this sterile skirt certain limb positions and certain surgical maneuvers occur far too close to nonsterile territory.

Approach

- Physeal-sparing distal radial entry is routinely obtained via the floor of the first dorsal compartment (alternately, the interval between the second and third dorsal compartments near the proximal base of the tubercle of Lister may be used).
- Physeal-sparing proximal ulnar entry is typically achieved via an anconeus starting point just off the posterolateral ridge of the olecranon. The true tip of the olecranon is avoided as an entry point because it needlessly violates an apophyseal growth plate, and a subcutaneous nail in this region often leads to painful olecranon bursitis.
- In complete both-bone fractures the radius is routinely approached first as it is considered to be the more difficult bone to reduce.
- No power instruments are required for completion of the procedure. Key instruments are a stout sharp-tipped awl and T-handled chucks that achieve a firm grip on the flexible nail such that it can be rotated as needed (FIG 6).

DISTAL RADIAL ENTRY POINT (PHYSEAL-SPARING)

- Using fluoroscopy (C-arm), a physeal-sparing distal radial incision is fashioned overlying the first dorsal compartment (TECH FIG 1A).
- Care is taken to protect branches of the superficial radial nerve. A short portion of the first dorsal compartment is opened.
- The tendons within the first dorsal compartment are retracted and protected before the awl engages the distal radius (TECH FIG 1B).
- After fluoroscopic confirmation of starting awl position, partial right and left rotations (not full turns) are used to

TECH FIG 1 • Repair of forearm fracture of the patient in Figure 3. A. Physeal-sparing incision fashioned with fluoroscopic assistance. B. The surgeon must identify and protect the abductor pollicis longus and extensor pollicis brevis. (continued)
gain satisfactory distal radial entry. A two-handed awl technique is used.

- Satisfactory intramedullary awl position is confirmed by a gentle “bounce” against the far cortex as well as fluoroscopic AP and lateral projections (TECH FIG 1C–E).
- The awl is temporarily left in its intraosseous position before insertion of the radial flexible intramedullary nail. Thus, the surgeon’s ability to judge both the portal location and the angle of nail entry will be facilitated by immediate sequential awl removal and nail tip insertion.

**Reduction and Nail Passage Within the Radius**

- The flexible nail for the radius is contoured such that it will re-establish appropriate radial bow. Nail contouring is gradual, smooth, and substantial. Acute bends in the nail should not be apparent (TECH FIG 2A–C).
- Entry into the distal radius entry site should be directly visualized, and the feel of the nail within the intramedullary canal offers distinct tactile feedback called “scrape.” Entry is further confirmed fluoroscopically (TECH FIG 2D).
- The radial nail is gently advanced up to the level of the fracture. Reduction is achieved via a combination of longitudinal traction and judicious use of AP compression with a radiolucent tool such as a vinyl Meyerding mallet (TECH FIG 2E).
- The nail is rotated to optimize nail passage across the fracture site (TECH FIG 2F–H), and then it is advanced to an appropriate depth within the proximal fragment (TECH FIG 2I).
TECH FIG 2 • (continued) D. Under direct visualization, the contoured radial nail is manually inserted into the previously prepared entry point. Distinctive intramedullary tactile feedback (“scrape”) should be detected and the implant advanced as far as possible using only the surgeon’s hands. Note the trajectory of the nail (tip points radially), as this nail orientation should be maintained during most of the procedure. E. Appropriate longitudinal traction needs to be applied by an assistant, as well as supplemental reduction forces such as that provided by the broad flat surface of a vinyl Meyerding mallet. F. The bent tip of the nail (the “fang”) approaches the fracture site after being advanced as far as possible without using a hammer. “Manual forces only” should be used as much as possible to advance the nail within the canal using a properly tightened T-handle or similar chuck. G. As the fang crosses the fracture site, proximal fragment intramedullary canal entry is often facilitated by nail rotation. At this point finesse is much, much more important than brute strength. H. Once the nail properly enters the proximal fragment, the position is radiographically confirmed and the nail is rotated back toward its “entry trajectory.” I. The nail is advanced to an appropriate level in the region of the radial neck and rotated so as to properly recreate radial bow. Restoration of radial bow can be quite striking when visualized under live C-arm imaging. When radial nail contouring is preserved during the insertion process, the nail should be rotated 180 degrees such that the fang points in an ulnar direction. If this position does not optimize radial bow, then live C-arm imaging will allow the surgeon to choose the nail rotation that does.
An entry point is selected on the lateral edge of the subcutaneous border of the proximal ulna. The skin is touched but not pierced by the awl (TECH FIG 3A).

Once correct position is confirmed fluoroscopically, the awl is used to gain percutaneous entry to the intramedullary canal of the proximal ulna (TECH FIG 3B).

A mildly contoured (i.e., nearly straight) flexible nail is inserted into the proximal ulna intramedullary canal (TECH FIG 3C).

Proper position within the proximal ulna is confirmed fluoroscopically (TECH FIG 3D).

The ulnar nail is cut such that it is subcutaneous yet easily palpable.

The ulna is reduced and the nail is passed across the fracture site in a manner similar to the radius. If open reduction becomes necessary, a simple Mueller (AO-type) approach to the ulna is used (exploiting the interval between the extensor carpi ulnaris and the flexor carpi ulnaris).

The ulnar nail is cut such that it is subcutaneous yet easily palpable.

PROXIMAL ULNA ENTRY POINT (PHYSEAL-SPARING)

The precontoured radial nail is rotated so as to optimize and normalize the anatomic bow of the radial shaft. This step is most dramatic when performed under several seconds of live fluoroscopic imaging.

Appropriate full-length forearm imaging must be performed at the end of the case to ensure an acceptable rotational relationship between the radial styloid and the bicipital tuberosity, as well as the ulnar styloid and the coronoid process.

Care must be taken when cutting the radial nail. If the nail is too short, removal will be difficult and dorsal compartment tendons adjacent to a sharp nail edge will be at risk. Thus, the nail should be cut to protrude beyond the tendons while still remaining subcutaneous.

Closure of the radial entry site is performed with absorbable subcutaneous and subcuticular suture and Steri-Strips. Care is taken to protect branches of the superficial branch of the radial nerve (TECH FIG 4A, B).

Light Xeroform, sterile gauze, and Tegaderm dressings are applied to the surgical sites (TECH FIG 4C–E).

A removable forearm fracture brace may also be applied to increase patient comfort (TECH FIG 4F).
TECH FIG 4 • My preferred closure, dressing, and splinting technique. A. Several interrupted absorbable sutures (typically 3-0 Vicryl) are used for closure of the subcutaneous and subcuticular portion of the radial wound. Steri-Strips are added for final wound closure (B), followed by Xeroform and sterile gauze (C), and a Tegaderm dressing (D). E. A similar dressing consisting of Xeroform, sterile gauze, and Tegaderm is applied to the proximal ulnar wound. F. A removable Velcro forearm fracture brace is applied at the end of the procedure.

PEARLS AND PITFALLS

<table>
<thead>
<tr>
<th>Question</th>
<th>Answer</th>
</tr>
</thead>
<tbody>
<tr>
<td>Which bone to reduce and fix first?</td>
<td>Once one bone is successfully reduced and stabilized via indirect techniques, achieving the same for the second bone will be more difficult. Thus, the radius should be stabilized first, as it is “deeper.” Then, if required, exposure of the nearly subcutaneous ulna is relatively easy.</td>
</tr>
<tr>
<td>How much flexible nail should be left extruding from the bone?</td>
<td>If it is too long, soft tissue adjacent to sharp nail edges is at risk. If it is too short, nail removal will be needlessly difficult.</td>
</tr>
<tr>
<td>At what point should efforts at closed reduction be abandoned in favor of a limited open reduction?</td>
<td>I use the “three strikes and you’re out” rule (three low-amplitude shots at crossing the fracture site) or the “11-minute rule.” Once either or both are violated, I convert the case to open reduction. Remember, cases of forearm compartment syndrome have been attributed to extended efforts at indirect reduction.</td>
</tr>
<tr>
<td>What if an intramedullary nail seems to become incarcerated after crossing the fracture site?</td>
<td>The surgeon should remove the nail and convert to one of a smaller diameter before creating new comminution or distracting the fracture site. Distracted fracture fragments may lead to nonunion.</td>
</tr>
<tr>
<td>What if sterile intraoperative radiographs suggest malrotation of one or both of the forearm bones?</td>
<td>The surgeon should back the offending nail up a bit and see if improved rotational alignment of the fracture fragments can be obtained via forearm rotation and T-handle chuck manipulation. The surgeon then re-advances the nail to hold position. If this does not work, the surgeon should consider switching to a smaller-diameter nail as intramedullary interference fit may be excessive.</td>
</tr>
<tr>
<td>When should the flexible nails be removed?</td>
<td>The originators of this technique suggest nail removal by about the sixth postoperative month. Forearm shaft fractures have the highest refracture rate (about 12%) of all pediatric fractures.</td>
</tr>
</tbody>
</table>

POSTOPERATIVE CARE

- Other than patients with open fracture, flexible nailing of the forearm can be performed as a outpatient procedure so long as there are absolutely no concerns about swelling or compartment syndrome.
- Oral prophylactic antibiotics may be continued for several doses postoperatively if desired, but usually an appropriately administered preoperative intravenous antibiotic (within 2 hours of the surgical incision) is all that is required.
- The patient is allowed immediate active elbow and hand motion. Concerns about rotational stability after flexible nail stabilization seem to have been vastly overstated, and above-elbow immobilization is not required.
- As there are no sutures to remove, outpatient follow-up may occur in 4 to 6 weeks (FIG 7A,B).
- The originators of this procedure have suggested that the nails be removed by about the sixth postoperative month (FIG 7C,D).
OUTCOMES

- At this time no randomized trials comparing flexible intramedullary nailing of forearm shaft fractures versus cast treatment have been conducted.
- A systematic review of English-language reports comparing flexible nailing to cast treatment found a significantly lower risk of forearm stiffness with nailing (25% stiffness with casting versus 5% with flexible nailing). This comes at the price of a higher rate of minor complications (21%) with surgery versus casting (6%).

COMPlications

- Sensory neurapraxia (usually the superficial branch of the radial nerve) occurs at a rate of at least 2% after flexible intramedullary nailing. These deficits are almost always temporary, resolving over weeks to months.
- The deep infection rate (osteomyelitis) after flexible intramedullary nailing of pediatric forearm shaft fractures is less than 0.5%; this can be compared to the reported 5% rate of osteomyelitis after plate fixation of similar fractures.
- Extensor tendon injury (especially the extensor pollicis longus) has been reported by multiple authors and may occur during nail insertion or nail removal as well as when tendons repetitively glide past a sharp nail tip (slowly sawing the tendon in two). Radial entry through the floor of the first compartment may minimize this complication (versus entry between the second and third compartments).
- In the clinical setting of forearm shaft fractures coexisting with ipsilateral humeral fracture (floating elbow), the incidence of compartment syndrome may be as high as 33%. When longer operative times are required (about 2 hours), a 7.5% rate of compartment syndrome has also been reported.
- Delayed union and nonunion are decidedly rare after flexible intramedullary nailing of pediatric forearm fractures. If either delayed union or nonunion occurs, there is usually some explanation, such as a technical error (eg, too large an intramedullary implant distracting the ulnar fracture site), infection, or neurofibromatosis.
- There should be a 5% or less chance of long-term forearm stiffness after flexible intramedullary forearm shaft fixation.

REFERENCES

DEFINITION
- Lateral condyle fractures refer to fractures of the lateral aspect of the distal humerus and may involve any or all of the following: metaphysis, physis, epiphysis, and articular surface.
- Fractures of the lateral condyle of the distal humerus account for 10% to 15% of all pediatric elbow fractures, second in frequency only to supracondylar distal humerus fractures.
- Nondisplaced fractures may hinge on the articular cartilage, making them more stable than their unstable, displaced counterparts.

ANATOMY
- Proximally, lateral condyle fractures almost always include some portion of the posterolateral metaphysis and then propagate along the physis before exiting through or around the ossification center of the capitellum.
- The articular cartilage may or may not be violated.
- The extensor carpi radialis longus and brevis muscles and lateral collateral ligament typically remain attached to the distal fragment.
- Anterior and posterior portions of the elbow joint capsule may be torn if there is significant displacement.
- Milch classified lateral condyle fractures based on the distal portion of the fracture line (FIG 1).
  - Milch type I fractures (the less common) traverse the metaphysis and physis as well as extend across the ossification center of the lateral condyle.
  - Milch type II fractures (the more common) extend from the metaphysis, through the physis, and exit in the unossified trochlea, medial to the capitellum ossification center. Displacement of the trochlear crista allows lateral translation of the forearm and increases the instability of this pattern.
- It is difficult to apply the Salter-Harris classification system to lateral condyle fractures since portions of the distal humeral epiphysis may not yet be ossified.
  - A fracture propagating from the metaphysis through the physis and then through the capitellum ossification center (Milch I) is analogous to a Salter-Harris type IV fracture.
  - A fracture that extends from the metaphysis through the physis and exits through the unossified trochlea medial to the capitellum ossification center (Milch II) may appear radiographically analogous to a Salter-Harris type II fracture, but its involvement of the articular cartilage is analogous to Salter-Harris types III and IV.
- A numeric classification system identifies fractures based on displacement.
  - Stage I fractures involve the metaphysis and physis but do not violate the articular cartilage, thus limiting their ability to displace.
  - Stage II fractures cross the articular surface but are minimally displaced.
- Stage III fractures are displaced fractures that cross the metaphysis, physis, and articular surface, frequently resulting in rotation of the distal fragment (FIG 2).

PATHOGENESIS
- The typical mechanism for a lateral condyle fracture is a fall on an outstretched hand.
- Adduction of a supinated forearm with the elbow extended can result in avulsion of the lateral condyle.
- Axial load of the forearm combined with valgus force can also propagate a fracture through the lateral condyle.
- Lateral condyle fractures usually occur as isolated injuries, although elbow joint subluxation and radial head or olecranon fractures may be associated.

NATURAL HISTORY
- The natural history of lateral condyle fractures depends on the initial fracture displacement as well as the long-term viability of the growing physis.
- Completely nondisplaced lateral condyle fractures may heal regardless of treatment.
- Nondisplaced fractures can displace over time if the articular cartilage is violated or if there is significant associated soft tissue injury.
- Delayed union can occur even in nondisplaced fractures and may be due to poor metaphyseal circulation, bathing of the fracture in synovial fluid, or tension on the condylar fragment by attached muscles.
- Fractures that heal in near-anatomic alignment can yield excellent functional and cosmetic outcomes.

FIG 1 • Milch classification of lateral condyle fractures is based on location. A. Type I fracture line passes through the ossific nucleus of the capitellum. B. Type II fracture line passes medial to the capitellar ossific nucleus into the trochlear groove.
Lateral condyle fractures associated with lateral physeal arrest can result in valgus deformity and tardy ulnar nerve palsy.

Lateral condyle fractures associated with central physeal arrest can result in a “fishtail” deformity due to continued growth medially and laterally but limited growth in between.

**PATIENT HISTORY AND PHYSICAL FINDINGS**

- Most patients report a fall, either on an outstretched hand or from some height, resulting in pain and inability to fully move the elbow.
- It may be difficult to obtain a history from a young child; therefore, parents or caregivers may need to be questioned.
- The clinician should be patient during the physical examination. Young children may be very fearful. The clinician should ask the child to point to what hurts most, and this part should be examined last. This allows the clinician to establish the patient’s trust and rule out other associated injuries.
- The clinician should look for obvious deformity, swelling, ecchymosis, and open wounds about the elbow.
- The clinician should assess for pulses and capillary refill.
- Sensation is assessed by comparison with the uninvolved side. Rather than stroking a finger and asking a young child, “Do you feel this?” the clinician can rub the same site on both hands and ask, “Does it feel the same or different?”
- Motor function is assessed by observing for spontaneous movement during the entire encounter. A scared child may refuse to move when asked by a physician but may demonstrate voluntary movement when asked by a parent or sibling. Being playful during the examination can help. For example, when testing for ulnar nerve function, asking a 5-year-old to show you how old he or she is may be more rewarding than asking the child to spread his or her fingers.
- The wrist and shoulder are palpated before touching the elbow.
- A single finger is used to gently palpate the olecranon, medial epicondyle, posterior humerus, lateral condyle, and radial head to try to localize the site of injury. Crepitus suggests displacement and instability of the fracture fragment.
- Increased motion during varus stress testing suggests instability of the fracture. Due to pain, however, this test can rarely be done on an awake child. It is often reserved for intraoperative assessment rather than preoperative diagnosis.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Radiographs of a suspected lateral condyle fracture should include anteroposterior (AP), lateral, and internal oblique views (FIG 3A–C).
- Valgus and varus stress radiographs can provide information about the stability of the fracture. Since such films are poorly tolerated in an awake child, they are rarely obtained outside of the operating room.
- For nondisplaced or minimally displaced fractures, magnetic resonance imaging (MRI) can be used to determine whether the articular surface is violated (FIG 3D).
- Arthrograms can provide detail about the articular congruity of lateral condyle fractures but are typically reserved for intraoperative assessment (FIG 3E).

**DIFFERENTIAL DIAGNOSIS**

- Contusion
- Lateral collateral ligament strain or sprain
- Radial head or neck fracture
- Supracondylar distal humerus fracture
- Transphyseal fractures
- Medial condyle fractures
- Proximal ulna or Monteggia fractures
- Elbow dislocation
- Child abuse

**NONOPERATIVE MANAGEMENT**

- Nonoperative management of lateral condyle fractures is typically reserved for nondisplaced or minimally displaced (less than 2 mm) fractures.
- The upper extremity is immobilized in a long-arm splint or cast with the elbow flexed 90 degrees and the forearm in neutral.
- Casts that are excessively heavy or short on the upper arm tend to slide down, thus increasing the risk of later displacement.
Follow-up radiographs should be obtained in 3 to 5 days to assess for further displacement. If displacement occurs, operative treatment is indicated. If the fracture remains nondisplaced, long-arm casting is continued for another week and then repeat radiographs are obtained. If still nondisplaced, the fracture is maintained in a long-arm cast for 3 to 4 weeks or until there is radiographic evidence of fracture union. Delayed union may occur, requiring up to 12 weeks of immobilization. Poor vascularization of the fracture fragment and bathing of the fragment in articular fluid may contribute to this phenomenon.

**SURGICAL MANAGEMENT**

- Surgery is recommended for lateral condyle fractures with more than 2 mm of displacement or rotational deformity that occurs acutely or during the early follow-up period of nonoperative treatment.
- Closed techniques with percutaneous pinning are reserved for minimally displaced fractures with a congruous articular surface confirmed by arthrography.
- Open surgery is required for displaced fractures.

**Preoperative Planning**

- Preoperatively, a careful neurovascular examination should be performed and documented. Fortunately, unlike supracondylar fractures, isolated lateral condyle fractures rarely have any associated neurovascular injury.
- Plain radiographs, including AP, lateral, and internal oblique views, should be adequate to make the decision to operate.
- Displacement of more than 2 mm indicates the need for surgical intervention.
- Displacement on two or more views suggests the need for open treatment.
- Displacement on only one view suggests that the fracture may be hinging on intact articular cartilage and may be treatable by percutaneous techniques.
- Fractures with borderline displacement (2 to 3 mm) may be better assessed under anesthesia, where stress radiographs or an arthrogram can guide treatment.

**Positioning**

- The patient is placed in the supine position on the operating table and general anesthesia is induced.
- The child should be brought to the edge of the operating table to facilitate fluoroscopic imaging of the operative limb (**FIG 4**).

**FIG 4 • Positioning the patient on the edge of the table allows easy access for fluoroscopy. The base of the unit may be used as an arm table.**
- Care must be taken to prevent the patient’s head from rolling off the table’s edge. Placing a foam doughnut under the head can provide stability.
- The receiving end of a standard fluoroscopy unit can be used as the operative table for the involved limb. Bringing the fluoroscopy unit up from the foot of the bed allows room for the surgeon and assistant to access the lateral side of the elbow.
- Alternatively, a hand table may be used and the fluoroscopy unit can be brought in after draping.
- A sterile tourniquet is recommended to allow full access to the elbow after draping.

**CLOSED REDUCTION AND PERCUTANEOUS PINNING**

- This technique is reserved for minimally displaced (2 to 4 mm) fractures.
- Fracture stability should be assessed under anesthesia with varus stress radiographs and arthrography.
- Two divergent smooth pins are recommended. Although 0.062-inch Kirschner wires are usually adequate, 5/64-inch Steinmann pins may be used in larger children.
- The first wire is placed through the skin into the lateral condyle to engage the metaphyseal fragment distally.
  - The wire should be directed from distal lateral to proximal medial, penetrating the cortex medially.
  - A second wire is then placed in a similar manner, diverging at the fracture site.
  - Increasing the distance between the wires at the fracture site increases stability (**TECH FIG 1A**).
- Wires may cross the ossification center of the capitellum to improve divergence (**TECH FIG 1B,C**).
- Occasionally, a third wire is needed. This wire is added if, after placing the first two wires, there is still motion at the fracture site when the elbow is varus stressed under fluoroscopy.
- The wires can be cut and bent 90 degrees outside of the skin.
- Sterile felt can be placed between the skin and the cut end of the wire. This helps prevent the cut end of the wire from digging into the skin during the postoperative swelling phase.

**TECH FIG 1** - **A.** Intraoperative fluoroscopic image showing two percutaneously placed Kirschner wires stabilizing a lateral condyle fracture. **B,C.** AP and lateral views of fracture treated with two divergent Kirschner wires.
OPEN REDUCTION AND INTERNAL FIXATION

- Unstable fractures require open treatment. This includes acutely displaced fractures as well as originally nondisplaced fractures that displace during early follow-up.

Exposure

- The lateral Kocher approach is used, although the dissection is typically facilitated by the rent in the brachioradialis that leads directly to the lateral condyle.
- A 5- to 6-cm curvilinear incision is used, with two thirds of the incision proximal and one third distal to the elbow joint (TECH FIG 2A).
- The interval is between the brachioradialis and the triceps down to the lateral humeral condyle. The anterior articular surface of the elbow joint is exposed by working from proximal to distal and retracting the soft tissues of the antecubital fossa anteriorly.
  - Although the fracture hematoma can obscure distinct muscular planes, a tear in the aponeurosis of the brachioradialis may lead directly to the fracture site.
- Dissection is kept anterior. Care should be taken to avoid stripping any of the soft tissues from the posterior aspect of the fracture fragment while the soft tissues are elevated off the anterior distal humerus, since this contains the blood supply to the lateral condyle epiphysis (TECH FIG 2B).
- Exposure is complete when the trochlear or medial extent of the fracture can be assessed anteriorly.

Fracture Reduction

- The goal of reduction is to achieve a congruent articular surface without any step-off.
- Lifting the anterior soft tissues with a Zenker retractor or similar instrument can allow direct visualization and inspection of the articular surface.
  - A Zenker retractor is narrow and angled, which makes it useful for lifting and retracting the anterior soft tissues without unnecessary stretch (TECH FIG 3A).
  - A small finger or elevator can be placed into the anterior elbow joint to palpate the trochlear–capitellar junction.
  - A common kitchen fork can be a useful instrument in this case.
  - Bending the outer tines back decreases the width of the fork and allows the central tines to fit into a small wound.
  - The central tines can be used to engage the distal fragment, which is then rotated and pushed into position.
  - Gaps between the tines allow room for placement of Kirschner wires (TECH FIG 3B).
- Alternatively, a Kirschner wire can be placed into the distal fragment and used as a joystick to help control the reduction.

**Fixation**

- Once the fragment is reduced, a smooth Kirschner wire is advanced from the metaphyseal portion of the distal fragment, across the fracture site, and into the medial cortex proximal to the fracture.
- A second Kirschner wire (or the original joystick wire) can now be advanced across the fracture site into the medial cortex.
- The wires can be cut and bent 90 degrees outside the skin to facilitate easy removal in the office in about 4 to 6 weeks.
- Alternatively, they can be cut very short and bent under the skin. This may decrease the risk of pin tract infection, but it requires a return to the operating room for pin removal (TECH FIG 4).
- If the wires are to be cut and bent outside the skin, the wires enter the skin through a separate stab site posterior to the incision.
- If a wire needs to be placed through the incision, it can be cut and the posterior skin can be pulled up and over the sharp cut end before closure.
- Increasing the gap between the wires at the fracture site increases rotational control.

- In older children with a larger metaphyseal fragment, a compression screw can be used rather than wires.
- The prominent screw head may be symptomatic after healing, however, thus requiring a return to the operating room for removal.
- Compressive threads across immature cartilage can impede growth in younger children.
- This technique, therefore, is usually reserved for delayed unions or nonunions.
- In many cases, closure of the lateral periosteum may be possible with sutures. Such closure may lessen the chance of lateral spur formation, add stability, and speed healing.

**TECH FIG 4** - After reduction and pinning, Kirschner wires may be cut and bent. Here they are to be buried under the skin.

---

### PEARLS AND PITFALLS

**Nonoperative management**

- Follow-up radiographs should be obtained within 3 to 5 days.
- Any loss of reduction suggests instability and prompts the need for operative intervention.

**Postoperative bone spur**

- A posterior or posterolateral metaphyseal bone spur frequently forms postoperatively. This is best seen on lateral radiographs. The bony prominence may give the clinical appearance of cubitus varus. Fortunately, this tends to improve over time and rarely requires intervention. Warning the parents initially of the probability of the occurrence can reduce anxiety later.

**Postoperative swelling**

- Placing felt over the cut, bend ends of the wires onto the skin decreases the risk of skin swelling over or pressing into their sharp tips while in the cast.
- Bivalving the cast decreases the risk of postoperative compartment syndrome.

**Delayed union and nonunion**

- This occurs more commonly in fractures treated nonoperatively.
- Prolonged casting of up to 12 weeks may be needed.
- If the fracture does not heal, open reduction with bone grafting may be necessary.

**Cubitus valgus and tardy ulnar nerve palsy**

- Premature closure of the lateral physis may lead to gradual deformity as the medial side continues to grow.
- Anatomic reduction decreases the risk.
- Follow-up radiographs can reveal the deformity.
- Nerve symptoms can take years to develop; therefore, patients should be counseled about signs and symptoms of ulnar nerve stretch.

**Cubitus varus**

- Unstable fractures treated nonoperatively can displace proximally and laterally, allowing the elbow to drift into a varus position.
- Doing careful early follow-up and fixing unstable fractures should prevent this.
POSTOPERATIVE CARE
- The arm is placed in a long-arm cast with the elbow flexed 90 degrees and the forearm in neutral to slight pronation.
- If there is significant swelling, the cast can be bivalved in the operating room and overwrapped the following week.
- Radiographs are obtained in 1 week to look for any loss of reduction.
- Wires can usually be pulled in 4 to 6 weeks.
- Authors have debated the exact timing. Although some have shown adequate healing by 3 weeks, a period of 4 to 6 weeks is generally required; the decision should be based on radiographic evidence of early callus.
- Gentle early active range of motion is encouraged after wire removal.
- A removable posterior splint can be made for children who will not comply with activity modifications.
- Physical or occupational therapy is rarely needed in children but may be recommended for those who fail to show improved range of motion.

OUTCOMES
- Patients who are treated quickly and whose fractures heal in an anatomic position with no subsequent growth arrest can expect excellent (90%) function and range of motion. Approximately 10% have minor loss of extension (10 to 15 degrees) at 1 to 2 years.
- Outcome studies following patients into adulthood are lacking.
- Patients who are treated with open reduction at 3 or more weeks after fracture are at greater risk for loss of range of motion (about 34 degrees), premature physeal closure, valgus deformity, tardy ulnar nerve palsy, and avascular necrosis, thus emphasizing the need for early treatment.

COMPLICATIONS
- Pin tract infections can occur but usually resolve after wire removal and oral antibiotics.
- Posterior or posterolateral metaphyseal bone spurs frequently form postoperatively and are best seen on lateral radiographs (FIG 5). Fortunately, these tend to smooth over time and are rarely symptomatic; thus, they usually require no treatment.
- Delayed union and nonunion are more common with nonoperative treatment than with surgical treatment.
- Malunion may occur in unstable fractures treated nonoperatively or in those with premature growth arrest.
- Avascular necrosis is more common after operative treatment than nonoperative management and is likely due to excessive posterior stripping that disrupts the epiphyseal blood supply.

REFERENCES

FIG 5 • Lateral radiograph showing postoperative bone spur projecting from posterior metaphysis.

- Tardy ulnar nerve palsy can develop slowly with progressive valgus deformity following premature growth arrest or nonunion.
DEFINITION
- Trauma to the medial aspect of the elbow may cause a medial epicondyle fracture, which is an injury to the apophysis of the medial epicondyle.

ANATOMY
- Medial epicondylar fractures involve the medial epicondylar apophysis on the posteromedial aspect of the elbow.
- The flexor-pronator muscle mass arises from this apophysis, including the palmaris longus, the flexor carpi ulnaris and radialis, the flexor digitorum superficialis, and one part of the pronator teres and the ulnar collateral ligament (FIG 1).³

PATHOGENESIS
- A direct blow to the medial aspect of the elbow may cause a fracture to the medial epicondyle, but this is rare.
- More commonly, a fall on an outstretched arm causes an avulsion of the medical epicondyle via tension generated by stretch of the muscles attaching to it. Elbow dislocation is frequently associated with a medial epicondyle fracture and may occur with spontaneous reduction at the time of the injury (FIG 2).
- Considerable force applied to the arm may cause elbow dislocation and associated disruption of the ulnar collateral ligament. This ligament, the principal stabilizing ligament of the elbow, can avulse the medial epicondyle, and the apophyseal fragment may sometimes become lodged in the elbow joint.³
- Overuse may cause a chronic stress-type injury or an apophysitis, an example of which would be Little League elbow.

NATURAL HISTORY
- The outcome of medial epicondyle fractures is related to the amount of fracture displacement and also the demands placed on the elbow by the patient.
- Minimally displaced fractures treated nonoperatively generally do well, especially if the patient is not an athlete or if the fracture involves the patient’s nondominant arm.
- Untreated displaced fractures may lead to chronic medial elbow instability and even recurrent elbow dislocations.
- Throwing athletes may have significant impairment in their sports activities.⁵

PATIENT HISTORY AND PHYSICAL FINDINGS
- For any elbow injury, the mechanism of injury should be sought, with particular attention to the details of a fall. In children this may be difficult to elicit, but often a witness may be available. Medial epicondyle fractures frequently arise from a fall.
- The two most important issues in the physical examination are to document neurovascular status and to assess for elbow stability. Determination of stability includes determination of whether the elbow is dislocated, which can be assessed clinically and confirmed radiographically.
- Assessment of medial elbow stability is often important in determining treatment.
A positive valgus stress test confirms medial elbow instability. Persistence of medial elbow stability may cause significant elbow disability in athletes or those doing heavy labor. Radiographs may confirm increased displacement of the medial epicondylar fragment.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**
- Standard anteroposterior (AP) and lateral radiographs of the elbow are required, but oblique views are often helpful to visualize the medial epicondyle, which is on the posteromedial aspect of the distal humerus.
- Widening of the apophysis may be the only sign of injury, so comparison views of the unaffected elbow are often helpful to assess for amount of displacement.
- If there is radiographic absence of the medial epicondyle and suspected joint incarceration, an arthrogram, CT scan, or MRI may be needed rarely.

**DIFFERENTIAL DIAGNOSIS**
- Medial condylar fractures
- Supracondylar fractures
- Elbow dislocation

**NONOPERATIVE MANAGEMENT**
- Smith in 1950 became a strong advocate of nonoperative management of this injury, pointing out that the fracture involved an apophysis rather than a physis, and thus future growth was not compromised. He also documented that imperfect reduction or even nonunion was not automatically associated with a poor outcome in terms of elbow function and strength.1
- A recent study from Sweden where all patients were treated nonoperatively showed 96% good to excellent results. Over 60% of the patients had a fibrous union or nonunion.3
- Two studies have compared nonoperative and operative treatment. Bede and associates1 found that nonoperative treatment had better outcomes than operative treatment.
  - Farsetti and coworkers4 demonstrated similar results in displaced fractures of nonoperative treatment and open reduction and internal fixation (ORIF) with Kirschner wires.
- Indications for nonoperative management of medial epicondyle fractures include patients who do not place high physical demands on their elbows, and most nondominant elbows.
- Nonoperative treatment encompasses splinting for 5 to 7 days or until acute soft tissue swelling resolves and then early active range of motion starting as soon as possible after the injury.
- Physical therapy may be required if range of motion is slow to return, but passive stretch may cause more injury and should be avoided.

**SURGICAL MANAGEMENT**
- Absolute indications
  - Incarceration of the medical epicondylar fragment in the joint
  - Associated elbow dislocation with ulnar nerve dysfunction
OPEN REDUCTION AND INTERNAL FIXATION WITH CANNULATED SCREW

- A skin incision about 4 cm long is made centered over the medial epicondyle after inflation of a tourniquet on the upper arm (TECH FIG 1A). Often with displaced injuries, the fractured fragment is just subcutaneous and little dissection is required.
- The ulnar nerve should be identified and carefully protected. Most experts do not recommend routine mobilization or transposition of the nerve.
- The fracture is identified and any organized hematoma is removed (TECH FIG 1B).
- The fracture is reduced with a towel clip. Elbow flexion and forearm pronation aid in reducing the fracture.
- Some surgeons suggest curettage of the apophyseal cartilage to expedite healing of the fracture, which may persist as a healed apophysis if this is not done. This tip may be especially advantageous in the throwing athlete who is eager to return to sports as soon as possible.
- The fracture is stabilized with one or two guide pins from the 4.0 cannulated screw set.

- Radiographs are checked to assess reduction and pin placement.
- The pin selected for overdrilling should not be in the olecranon fossa. The second pin provides rotational stability of the fragment during drilling and screw placement.
- An appropriate-length screw is selected and inserted over the guide pin, stabilizing the fracture.
- A washer may be used to provide a wide surface area of fixation and prevent screw head migration.
- AP and lateral intraoperative radiographs should confirm reduction and screw placement position (TECH FIG 1C–G).
- Elbow stability should be checked and full range of motion confirmed before closure.
- Standard skin closure is carried out, and the arm is splinted or casted at 90 degrees of elbow flexion.

TECH FIG 1 • A. Incision with ulnar nerve identified. B. The fracture fragment is mobilized. C. Fluoroscopic image showing two pins spanning the fracture fragment for rotational stability. D,E. Cannulated screw fixation shown fluoroscopically. F,G. Radiographs showing healed fracture. Heterotopic bone formation anteriorly can be seen on the lateral radiograph.
Chapter 3 ORIF OF FRACTURES OF THE MEDIAL EPICONDYLE

**SUTURE FIXATION**
- Should the fracture cause comminution of the medial epicondyle, repair with sutures may be warranted in a high-demand patient or one with medial instability.
- This would involve sutures placed directly in the tendinous tissue and secured to the periosteum adjacent to the bed from which the epicondyle was avulsed.

**EXTRACTION OF MEDIAL EPICONDYLE FROM ELBOW JOINT: ROBERTS TECHNIQUE**
- A valgus stress is applied to the elbow with the forearm supinated.
- The wrist and fingers are dorsiflexed.
- As the position is reached, the fragment should be dislodged from the joint.
- This technique is most effective in the first 24 hours after the injury, before much muscle spasm occurs.

**PEARLS AND PITFALLS**

<table>
<thead>
<tr>
<th>Medial epicondyle fracture fragment should be fixed with a cannulated screw if possible rather than pins to have rigid fixation permitting early motion.</th>
<th>The surgeon must beware of a medial epicondyle that is absent on radiography: it may be trapped in the joint.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Elbow motion is encouraged as soon as possible after surgery to minimize postoperative stiffness.</td>
<td>The surgeon must document radiographically that the internal fixation is not in the olecranon fossa, where it may block elbow extension.</td>
</tr>
</tbody>
</table>

**POSTOPERATIVE CARE**
- Postoperative management after open reduction of medial epicondyle fractures depends on the type and stability of the fixation of the epicondylar fragment.
- For ORIF with screws, initial splinting for 3 to 5 days in about 50 to 60 degrees of flexion is recommended, followed by early active range of motion.
- Some authors recommend a removable brace preventing valgus stress but permitting full flexion and extension for 4 weeks.
- In one recent series on young athletes with this injury repaired with screw fixation, active range of motion out of the brace continued from weeks 5 to 8 postoperatively. At 8 weeks noncontact sports were allowed, and return to full activity was possible at 12 weeks after surgery.

**OUTCOMES**
- Eight adolescent athletes undergoing ORIF with screw fixation for this fracture had excellent results with no residual valgus instability and full return to all sports. One patient had a loss of 5 degrees of hyperextension, but all other patients had recovery of full range of motion.
- In another series, 21 of 23 patients treated operatively had recovery of full movement, whereas only 14 of 20 patients treated nonoperatively had full range of motion.
- A recent series of operative treatment and early motion in 25 patients with displaced fractures showed good to excellent results in all patients.

**COMPLICATIONS**
- Failure to diagnose joint entrapment of the medial epicondyle fracture
- Ulnar nerve dysfunction
- Loss of range of motion
- Nonunion
- Myositis ossificans

**REFERENCES**
DEFINITION
- A supracondylar fracture that requires open reduction is one that cannot be treated with closed reduction and percutaneous pinning.

ANATOMY
- A very thin area of bone connects the medial and lateral columns of the distal humerus. This makes the area prone to fracture. The coronoid fossa is located anteriorly and the olecranon fossa is located posteriorly.
- The neurovascular anatomy to consider for an open reduction includes:
  - The ulnar nerve passes behind the medial epicondyle.
  - The radial nerve courses from posterior to anterior just above the olecranon fossa.
  - The brachial artery and median nerve pass through the antecubital fossa.

PATIENT HISTORY AND PHYSICAL FINDINGS
- The patient history is the same for supracondylar fractures being treated by closed methods.
- Tenting of the skin may indicate an open reduction is needed. This may represent buttonholing of the proximal fragment through the periosteum and brachialis muscle, making closed reduction difficult.
- A careful neurovascular examination must also be performed.

SURGICAL MANAGEMENT
- Indications for open treatment of a supracondylar fracture include an open fracture, an irreducible fracture, and a compromised vascular supply to the hand that does not reconstitute with reduction by closed means.
- The timing for surgical intervention has been a matter of debate. Many surgeons believe that prompt pinning or open reduction is optimal. Some newer articles have been published finding no significant increase in complication rates with delayed treatment.2,3

Preoperative Planning
- During preoperative planning, the surgeon must consider the reasons why an open procedure is necessary. This will help guide the approach.
- Other factors for consideration include the pin size for maintaining the reduction once the fracture is reduced. In general, 0.062-mm wires are used for all but the oldest children. More importantly, at least three pins should be used for type III fractures if they are going to be pinned with lateral entry pinning.

Positioning
- The patient is placed supine on the operating table. A hand table attachment is valuable. A sterile tourniquet is placed on the child’s arm after preparation and draping. The surgeon should make sure that the fluoroscope can be moved easily into and out of the operative field to assist with pinning of the fracture.

Approach
- The first factor to consider in determining the approach is the direction of displacement of the distal fragment. This helps guide placement of the incision.
  - In general, a transverse anterior incision through the antecubital fossa is the most useful and cosmetic.
  - If more visualization is needed, this incision can be extended medially or laterally based on displacement, but this is rarely necessary.
  - Extension of the incision on the opposite side of the displacement of the distal fragment allows for removal of soft tissue obstacles to reduction.
  - If there is a suspicion of neurovascular compromise, the anterior approach provides the best exposure.
  - An inability to reduce the fracture may indicate that the proximal fragment has buttonholed through the brachialis muscle. Again, an anterior approach is the most useful exposure to reduce this deformity.
  - Some surgeons have advocated a posterior approach for severely comminuted fractures.4 However, other surgeons strongly believe that a posterior approach risks compromising the blood supply to the distal fragment and should be avoided.5
OPEN REDUCTION THROUGH AN ANTERIOR APPROACH

Incision and Dissection

- Once the patient has been prepared and draped, the tourniquet is inflated.
- A transverse incision is made across the antecubital fossa (TECH FIG 1A).
- Blunt dissection continues through the subcutaneous and fatty tissue. Care must be taken in dissecting as the neurovascular bundle may be located in a nonanatomic place; it may be immediately in the subcutaneous tissue and at risk for damage during initial dissection (TECH FIG 1B).
- Dissection proceeds until the metaphyseal spike is encountered. It is covered by a small amount of tissue and parts of the brachialis muscle that may be torn (TECH FIG 1C).
- It is at this point that the neurovascular bundle should be located, if it has not yet been identified. This usually involves dissecting across the anterior aspect of the metaphyseal spike. This step should not be omitted even if there is no vascular compromise. Once the vessels are identified, they should be retracted out of the field.

Fracture Reduction

- Defining the outline of the distal fragment can be the most challenging aspect of the procedure. It is posterior and lateral and the periosteum is folded over its surface (TECH FIG 2).
- Reduction is obtained by reaching into the fracture site with a hemostat and getting hold of the cut edge of the periosteum. This cut edge is extended with scissors to increase the size of the buttonhole and helps to free up the distal fragment. The distal fragment is then brought anteriorly and reduced to the shaft fragment, which is maneuvered back through the buttonhole into its resting position posterior to the brachialis muscle.
- Alternatively, the surgeon can hold his or her thumb on the proximal fragment and push downward while an assistant applies traction to the forearm with the elbow flexed at 90 degrees. A periosteal elevator can be used as a lever to assist the reduction.

Pinning

- Once a reduction has been obtained, the fracture is fixed with smooth Kirschner wires. This is accomplished in the
POSTOPERATIVE CARE

- Sterile dressings are applied over the incision.
- A strip of Xeroform dressing can be wrapped around the pins, followed by fluff dressings.
- The elbow is splinted in 60 to 90 degrees of flexion with a neutral forearm.
- The patient is admitted overnight for observation. Often a long-arm cast can be placed safely the next day, with the arm flexed about 80 degrees. This cast can be maintained until the pins are removed 3 or 4 weeks after surgery.
- The patient can then be placed back into a sling and started on gentle range-of-motion exercises out of the sling for another 2 weeks.
- The child can then start to use the arm normally.
- Formal physical therapy is usually not necessary.

OUTCOMES

- It is generally agreed that prompt attention to reduction and stabilization of supracondylar fractures results in better outcomes and fewer complications.
- Postoperative loss of reduction is uncommon. However, children with supracondylar fractures that have been treated with open reduction generally take longer to regain their elbow motion than children treated with closed pinning. Families should be advised about this longer period of elbow stiffness in the immediate postoperative period.
- A 2001 study of 862 supracondylar fractures treated with open reduction found 55% excellent results, 24% good results, 9% fair results, and 12% poor results 5.8 months after injury.

PEARLS AND PITFALLS

| Indications | The surgeon should have a good understanding of why an open procedure is necessary. The primary indications for an open reduction are interposed tissue in the fracture site and vascular compromise that does not improve with closed reduction and percutaneous pinning. |
| Neurovascular structures | The neurovascular bundle can be located anywhere within the operative field and must be identified even if there is no suspicion of compromise. |
| Reduction of the fracture | The distal fragment often can be palpated but not seen as it is hidden by the overlying periosteum. The surgeon should expand the buttonhole through the periosteum for better visualization. |
| Fracture pinning | Pins should be maximally separated at the fracture site if three lateral pins are used. Convergent pins are not stable. If medial and lateral pins are used, the surgeon should engage the medial and lateral columns of the distal fragment. |
COMPLICATIONS

- Complications can result from the injury itself or from surgery.
- The risk of infection is decreased with the use of perioperative antibiotics.
- Iatrogenic neurovascular injury
  - Identification of neurovascular structures is crucial.
  - The ulnar nerve is susceptible to injury if a medial pin is used.
- Compartment syndrome
  - The child should be kept overnight for observation and the surgeon should make sure that serial neurovascular examinations are performed.
  - The first sign of compartment syndrome in a child is usually increased pain, or increased pain medication requirements.
  - The children most at risk are those who had compromised blood flow to the hand immediately after injury.
  - Children who have a median nerve injury often do not complain of the pain because of the sensory deficit.
- Loss of motion
  - Although rare, some loss of full extension has been reported.
  - If there is excessive posterior angulation at the time of healing, some loss of full flexion can occur.
  - Cubitus valgus and cubitus varus
  - Varus angulation is mostly cosmetic.
  - Valgus deformity can cause loss of full elbow extension and can result in tardy ulnar nerve palsy.
  - Myositis ossificans is rare and should resolve in 1 to 2 years.

REFERENCES

DEFINITION
- Supracondylar fractures of the humerus are common injuries in children. As many as 67% of children hospitalized with elbow injuries have supracondylar fractures; supracondylar fractures of the humerus represent 17% of all childhood fractures.\(^4,5\)
- The peak age at fracture is 5 to 7 years.
- The cause of injury is most commonly a fall from height (70%).
- The vast majority of supracondylar fractures of the humerus are of the extension type (97%).\(^3\) Flexion-type injuries also occur.
- Open injuries occur in 1% of cases. Concurrent fractures, most commonly involving the distal radius, scaphoid, and proximal humerus, occur in 1% of cases. Associated neurovascular injuries can occur, with preoperative nerve injury existing in 8% of cases and vascular insufficiency present in 1% to 2% of cases.\(^2\)

ANATOMY
- The periosteum most commonly fails anteriorly with extension-type supracondylar fractures of the humerus. With posteromedial displacement, the periosteum also fails laterally. Therefore, with posteromedially displaced fractures, forearm pronation can aid in the reduction (FIG 1).
- With posterolateral displacement, the periosteum also fails medially. Forearm supination usually aids in the reduction of these posterolaterally displaced fractures.
- The direction of displacement has implications for which neurovascular structures are at risk from the penetrating injury of the proximal metaphyseal fragment (FIG 2).
  - Medial displacement of the distal fragment places the radial nerve at risk.
  - Lateral displacement of the distal fragment places the median nerve and brachial artery at risk.
  - The ulnar nerve courses through the cubital tunnel posterior to the medial epicondyle. It is at particular risk with flexion-type fractures or when a medial pin is placed for fracture fixation.
  - The ulnar nerve subluxates anteriorly as the elbow is flexed. Therefore, the elbow should be relatively extended if a medial pin is placed for fracture fixation.

PATHOGENESIS
- Supracondylar fractures of the humerus generally occur as a result of a fall onto an outstretched hand with the elbow in full extension.
  - The distal humerus is very thin at the supracondylar region, a critical factor in producing a consistent injury pattern and failure in the supracondylar humeral region.
  - During a fall with the elbow in full extension, the olecranon in its fossa acts as a fulcrum.
  - The capsule, as it inserts distal to the olecranon fossa and proximal to the physis, transmits an extension force to this region, resulting in failure and fracture.
  - With the elbow in full extension and the elbow becoming tightly interlocked, bending forces are concentrated in the distal humeral region.
  - Increased ligamentous laxity, leading to hyperextension of the elbow, may be a contributing factor to this injury pattern.

NATURAL HISTORY
- The physis of the distal humerus contributes little to the overall growth of the humerus (20% of the humerus); therefore, the remodeling capacity of supracondylar fractures of the humerus is limited. Near-anatomic reduction of these fractures is important.
- The majority of supracondylar fractures of the humerus (other than extension type I fractures) are unstable; therefore, stabilization in the form of cast immobilization or preferably operative fixation is usually necessary.

PATIENT HISTORY AND PHYSICAL FINDINGS
- Evaluation of the child with an elbow injury must include an overall assessment to look for associated trauma (especially in the proximal humerus and distal radius regions) as well as associated neurovascular injury.
- The physical examination may reveal swelling, tenderness, ecchymosis, and deformity. The pucker sign, which occurs as a result of the proximal fracture fragment spike penetrating through the brachialis and anterior fascia into the subcutaneous tissue, may be present.
- Thorough neurovascular examination of the involved extremity is critical. Physical examinations to perform include:
  - Assessing for potential associated injury to the ulnar nerve. Finger abduction and adduction (interossei) strength is tested. Sensation in the palmar little finger is tested.
  - Assessing for potential associated injury to the radial nerve. Finger, wrist, and thumb extension (extensor digitorum communis, extensor indicis proprius, extensor carpi radialis longus and brevis, extensor carpi ulnaris, extensor pollicis longus) is tested. Sensation in the dorsal first web space is tested.
  - Assessing for potential associated injury to the median nerve. Thenar strength (abductor pollicis brevis, flexor
DIFFERENTIAL DIAGNOSIS

- Fracture of elbow (other than involving the supracondylar humeral region)
- Salter-Harris fractures involving the elbow
- Nursemaid’s elbow
- Infection

NONOPERATIVE MANAGEMENT

- The indications for nonoperative management of supracondylar fractures of the humerus are limited to nondisplaced fractures (type I).
- The anterior humeral line transects the capitellum on the lateral radiograph.
- The Baumann angle is >10 degrees or equal to the other side.
- The olecranon fossa and medial and lateral cortices are intact.
- Nonoperative management consists of immobilization of the elbow in no more than 90 degrees of flexion in a splint or cast.
- As the brachial artery becomes compressed with increasing flexion of the elbow, the clinician must ensure that the distal radial pulse is intact and that there is adequate perfusion distally.
- Historically, some supracondylar fractures of the humerus were managed with traction (overhead versus side). With the relative safety of percutaneous pinning techniques, however, the use of traction has been limited.

SURGICAL MANAGEMENT

- The two main options for percutaneous pin fixation are the lateral-entry pin and crossed-pin techniques.
- Most fractures can be stabilized successfully by the lateral-entry pin technique.6
- Two pins are usually adequate for type II fractures; three pins are recommended for type III fractures.
- Biomechanical studies have revealed comparable stability in the lateral-entry and crossed-pin techniques.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Initial imaging studies should include plain radiographs of the elbow—anteroposterior (AP), lateral, and sometimes oblique views.
- Comparison views of the contralateral elbow are sometimes helpful.
- The fat-pad sign, particularly posterior, represents an intra-articular effusion and can be associated with a supracondylar fracture of the humerus (53% of the time) (FIG 3A).7
- On the AP view, the Baumann angle correlates with the carrying angle and should be 70 to 78 degrees or symmetric with the contralateral elbow (FIG 3B).
- On the lateral view, the anterior humeral line (line drawn along the anterior aspect of the humerus) should intersect the capitellum (FIG 3C).
- The most commonly used classification system, the Gartland classification, is based on plain radiographic appearance:
  - Extension type I: nondisplaced
  - Extension type II: capitellum displaced posterior to anterior humeral line with variable amount of extension and angulation; posterior cortex of the humerus is intact
  - Extension type III: completely displaced with no cortex intact
  - Flexion type

FIG 1 • Reduction of a posteromedially displaced supracondylar fracture of the humerus. Pronation of the forearm closes the hinge and aids in reduction.

FIG 2 • Relationship to neurovascular structures. The proximal metaphyseal spike penetrates laterally with posteromedially displaced fractures and places the radial nerve at risk. With posterolaterally displaced fractures, the spike penetrates medially and places the median nerve and brachial artery at risk.

FIG 3A • Fat-pad sign. Excess fat in the olecranon fossa may cause the olecranon process to appear higher than normal, representing an intra-articular effusion or a type II fracture. The olecranon process should align with the capitellum on the AP view, bilaterally.

FIG 3B • Baumann angle. The angle between the capitellum and radial head on the lateral radiograph of the elbow should be 70 to 78 degrees. The Baumann angle is symmetric on the normal side and is equal or greater than 10 degrees on the injured side.

FIG 3C • Anterior humeral line. The anterior humeral line intersects the capitellum on the lateral radiograph of the elbow.
An advantage of the lateral-entry pin technique is the significantly lower risk of iatrogenic nerve injury. The ulnar nerve is at risk when pins are inserted medially (5% to 6% risk).

The crossed-pin technique may be indicated if persistent instability is noted intraoperatively after placement of three lateral-entry pins.

Preoperative Planning
- Displaced supracondylar fractures of the humerus (including Gartland type II and III) require reduction. Usually, reduction can be achieved by closed means. The preferred method for fixation is percutaneous pinning.
- Indications for open reduction of supracondylar fractures of the humerus are limited but include open injuries, fractures irreducible by closed means, and fractures associated with persistent vascular compromise even after adequate closed reduction.
- All imaging studies are reviewed. A high index of suspicion for associated fractures, especially of the forearm, is important; if present, there is an increased risk of compartment syndrome.
- Complete preoperative neurologic and vascular examination is performed and documented.
- The contralateral arm should be examined, and the carrying angle of the contralateral arm should be noted.
- The timing of surgery remains controversial. Recent retrospective studies suggest that a delay in treatment of the majority of supracondylar fractures is acceptable.¹
- Fractures with “red flags” (eg, significant swelling and signs of neurologic and especially vascular compromise or an associated forearm fracture) usually require urgent treatment.

Positioning
- The patient is positioned supine on the operating room table.
- The fractured elbow is placed on a radiolucent armboard (FIG 4A). The arm should be far enough onto the armboard to allow for complete visualization of the elbow and distal...
humerus. In smaller children, the child’s shoulder and head may need to rest on the armboard as well.

- The wide end of a fluoroscopy unit is sometimes used as a table.
- In cases of severe instability of the fracture, use of the fluoroscopy unit as an armboard is suboptimal because reduction of the fracture is frequently lost with rotation of the arm, which is needed for AP and lateral views of the elbow.
- The fluoroscopy monitor is placed opposite to the surgeon for ease of viewing (FIG 4B).

**CLOSED REDUCTION**

- Traction is applied with the elbow in 20 to 30 degrees of flexion (TECH FIG 1A) to prevent tethering of the neurovascular structures over the anteriorly displaced proximal fragment.
- For severely displaced fractures, where the proximal fragment is entrapped in the brachialis muscle, the “milking maneuver” is performed (TECH FIG 1B).
  - The soft tissue overlying the fracture is manipulated in a proximal to distal direction.
- Once length is restored, the medial and lateral columns are realigned on the AP image.
  - Varus and valgus angular alignment is restored.
  - Medial and lateral translation is also corrected.
- For the majority of fractures (ie, extension type), the flexion reduction maneuver is performed next (TECH FIG 1C).
  - The elbow is gradually flexed while applying anterior pressure on the olecranon (and distal condyles of the humerus) with the thumbs.
- The elbow is held in hyperflexion as the reduction is assessed by fluoroscopy.
- Reduction is adequate if the following criteria are fulfilled:
  - The anterior humeral line crosses the capitellum.
  - The Baumann angle is >10 degrees or comparable to the contralateral side.
  - Oblique views show intact medial and lateral columns.
- The forearm is held in pronation for posteromedial fractures.
- The forearm is held in supination for posterolateral fractures.
- For unstable fractures, the fluoroscopy machine instead of the arm is rotated to obtain lateral views of the elbow (TECH FIG 1D).
**LATERAL-ENTRY PIN TECHNIQUE**

- Once satisfactory reduction is obtained, K-wires can be inserted percutaneously for fracture stabilization.
  - 0.062-inch smooth K-wires are commonly used.
  - Smaller or larger sizes may be used depending on the size of the child.
- The goals of the lateral-entry pin technique are to maximally separate the pins at the fracture site and to engage both the medial and lateral columns (TECH FIG 2A–C).
  - The pins can be divergent or parallel.
  - Sufficient bone must be engaged in the proximal and distal fragments.
  - Pins may cross the olecranon fossa.
- As a general rule, two pins are adequate for type II fractures; three pins are recommended for type III fractures.
- The K-wire is positioned against the lateral condyle without piercing the skin (TECH FIG 2D).
  - The starting point is assessed under AP fluoroscopic guidance.
  - The K-wire is held freehand to allow maximum control.
- Once a satisfactory starting point and trajectory are confirmed, the K-wire is pushed through the skin and into the cartilage.
  - The cartilage of the distal lateral condyle functions as a pincushion.
- The starting point and trajectory are assessed by AP and lateral fluoroscopic guidance.
- When satisfactory starting point and trajectory are confirmed, the pin is advanced with a drill until at least two cortices are engaged.
  - At this point, the reduction is again assessed.
  - The reduction must appear satisfactory on AP, lateral, and two oblique views.
  - The elbow is rotated to allow for oblique views of the medial and lateral columns.
- Additional pins are inserted (TECH FIG 2E–H).
  - The elbow is stressed under live fluoroscopy in both the AP and lateral planes.
- Once satisfactory reduction and stability are confirmed, the vascular status is again assessed.
  - Upon completion, the pins can be bent and cut approximately 1 to 2 cm off the skin.
TECH FIG 2 • A–C. Lateral-entry pin technique: optimal pin configuration. The pins are separated at the fracture site to engage the medial and lateral columns. A. Optimal pin configuration for two pins (AP view). B. Optimal pin configuration for three pins (AP view). C. Optimal pin configuration (lateral view). D. The pin is held freehand. Once starting point and trajectory are confirmed under fluoroscopic guidance, the pin is pushed through the skin and into the cartilage. E,F. Assessment of coronal alignment on AP and lateral views. G. Externally and internally rotated oblique views are used to assess the medial and lateral columns. H. Stress fracture. The elbow should be stressed under live fluoroscopy to confirm adequate stability.
CROSSED-PIN TECHNIQUE

- If satisfactory stability cannot be achieved by lateral-entry pins or if the surgeon is more comfortable with lateral- and medial-entry pins, the crossed-pin technique can be performed.
- The lateral-entry pins are inserted first: this will allow the elbow to extend when placing the medial-entry pins.
  - The ulnar nerve subluxates anteriorly with increasing flexion of the elbow; therefore, the ulnar nerve may be at risk when medial-entry pins are placed with the elbow in 90 degrees or more of flexion.
  - After insertion of the lateral-entry pins, the elbow is extended to 20 to 30 degrees of flexion (TECH FIG 3A).
  - A small incision is made over the medial epicondyle.
  - Blunt dissection is performed down to the level of the medial epicondyle.
  - A pin is positioned on the medial epicondyle (TECH FIG 3B).
  - The starting position and trajectory are assessed under fluoroscopic guidance.
  - When a satisfactory starting point and trajectory are confirmed, the pin is advanced with a drill until at least two cortices are engaged (TECH FIG 3C,D). The medial column should be engaged.
  - Ideally, the pin should be separated from the other pins maximally at the fracture site.
  - The reduction and stability of the fracture are assessed just as with the lateral-entry pin technique. The vascular status is similarly evaluated.

TECH FIG 3 • Crossed-pin technique. A. To minimize risk of iatrogenic injury to the ulnar nerve, the elbow is extended to 20 to 30 degrees of flexion before the pins are inserted medially. B. The starting point is on the medial epicondyle. C,D. The medial pin should engage the medial column and at least two cortices.
CLOSED REDUCTION AND PERCUTANEOUS PINNING OF SUPRACONDYLAR FRACTURES OF THE HUMERUS

Chapter 5

POSTOPERATIVE CARE

The arm is immobilized, preferably in a cast (sometimes a splint), with the elbow in 45 to 60 degrees of flexion.

- Flexing the elbow to 90 degrees, as is used for most other casting, will increase the risk of compartment syndrome because the fracture reduction is stabilized by the pins, not the cast.
- Sterile foam may be directly applied to the skin before cast application to allow for postoperative swelling.
- The arm is immobilized for 3 to 4 weeks, with follow-up evaluations at 1 and 3 (or 4) weeks. Postoperative radiographs (AP and lateral views) are obtained.
- Pins are usually discontinued at 3 to 4 weeks postoperatively.
- Range-of-motion exercises are initiated shortly after pins and immobilization are discontinued.
- Return to full activity typically occurs by 6 to 8 weeks postoperatively.

OUTCOMES

Studies have suggested that treatment of supracondylar fractures can be delayed without significant added risk in appropriately selected patients.

- Multiple studies have reported on the efficacy and high safety profile of the lateral-entry pin technique.
- A consecutive series of 124 patients with type II and type III supracondylar fractures of the humerus were evaluated. A Fractures were stabilized by the lateral-entry pin technique.
- There were no cases of malunion or iatrogenic nerve injury.
- One patient had a pin-track infection.

COMPLICATIONS

- Elbow stiffness
- Infection
- Vascular injury
- Neurologic injury
- Malunion
- Nonunion
- Avascular necrosis
- Myositis ossificans

REFERENCES

DEFINITION
- Radial neck fractures are extra-articular fractures of the radius proximal to the bicipital tuberosity.
- Radial neck fractures are most common in children 9 to 12 years old and represent 14% of elbow fractures in children. The physis is typically involved as a Salter-Harris I or II pattern, yet Salter-Harris III and IV patterns also occur. Alternatively, the fracture often is extraphyseal, through the metaphysis.
- Intra-articular radial head fractures are less common elbow injuries in patients with open physes than in skeletally mature patients (7% vs. 52%). The Wilkins classification of radial head and neck fractures is based on the mechanism of injury and the pattern of the fracture, specifically whether there is physeal or articular involvement:
  - Type I: Valgus injury
    - A: Physeal injury—Salter-Harris I or II
    - B: Intra-articular—Salter-Harris III or IV
    - C: Metaphyseal fracture
  - Type II: Elbow dislocation
    - D: Fracture occurred during dislocation
    - E: Fracture occurred during reduction
- The O’Brien and Judet classifications of radial neck fractures are based on degree of angulation.
  - O’Brien classification
    - Type I: Less than 30 degrees
    - Type II: 30 to 60 degrees
    - Type III: More than 60 degrees
  - Judet classification
    - Type I: Undisplaced
    - Type II: Less than 30 degrees
    - Type III: 30 to 60 degrees
    - Type IVa: 60 to 80 degrees
    - Type IVb: More than 80 degrees

PATHOGENESIS
- The most common mechanism of radial neck fractures is a valgus and axial force to the elbow caused by a fall on an outstretched hand. This mechanism results in a lateral compression and a medial traction injury. The actual plane of maximal radial head angulation depends on the forearm position of supination or pronation at the time of impact.
- The other mechanism of injury is an elbow dislocation, where the fracture occurs either during the dislocation (radial head anterior) or during the elbow reduction (radial head posterior).
- Associated injuries, such as medial collateral ligament rupture or occult elbow dislocation, occur in 30% to 50% of radial neck fractures.
- Chronic stress fractures of the radial head and neck can occur with repetitive valgus loading, such as overhead throwing.

NATURAL HISTORY
- The prognosis for radial neck fractures depends on the energy of injury, the amount of displacement, and the presence of any associated injuries.
- Patients with minimal fracture displacement and a congruent joint generally have a favorable prognosis, while more severe alterations of normal joint anatomy can severely impede elbow range of motion unless reduced.

ANATOMY
- The radial head articulates with the capitellum and the radial notch of the ulna. The radial neck is extra-articular and has a normal 15 degrees of angulation on anteroposterior (AP) and 5 degrees on lateral radiographic views. The radial head ossific nucleus appears at about 4 years of age.
- The proximal radioulnar joint is stabilized by the annular ligament and the accessory collateral ligament.
- There are no muscular attachments to the radial neck. The blood supply is derived from the adjacent periosteum.
- The radial nerve gives rise to the superficial radial nerve and the posterior interosseous nerve at the level of the lateral condyle. The posterior interosseous nerve travels distally anterior to the radial head and neck, enters the arcade of Frohse 2.6 cm distal to the radial head (FIG 1), and submerges between the superficial and deep fibers of the supinator 6.7 cm distal to the radial head. The radial recurrent artery originates from the radial artery and travels toward the lateral epicondyle in the opposite direction along the path of the radial nerve, on the anteromedial surface of the supinator.

FIG 1 • The posterior interosseous nerve courses volar to the radial head and neck and enters the arcade of Frohse about 2.6 cm distal to the articular surface of the radial head.
PATIENT HISTORY AND PHYSICAL FINDINGS

- Elucidating the mechanism of injury is important to truly understand the personality of the fracture, which can help in directing treatment. Higher-energy mechanisms are more likely to be associated with concomitant injuries. Elbow dislocations that have reduced before presentation are not uncommon, so it is helpful to ask the patient and family whether a marked deformity was noted at the time of injury.
- Carefully palpating each anatomic area in the elbow to find the points of maximal tenderness helps diagnose the fracture as well as additional injuries. Associated injuries include medial collateral ligament tears, medial epicondyle fractures, ulna fractures, and supracondylar humerus fractures. A neurologic evaluation assesses distal radial, medial, and ulnar nerve motor and sensory function.
- Assessing elbow stability and range of motion can help determine the need for treatment.
  - Valgus instability indicates a medial elbow injury in addition to an unstable radial neck fracture.
  - Blocks in forearm rotation, in particular pronation, are typically due to loss of congruity of the radioulnar joint and indicate a need for reduction.
  - Stability and range-of-motion assessment may necessitate either an intra-articular anesthetic injection or an examination under anesthesia.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- AP, lateral, and oblique radiographs often show radial neck fractures well (FIG 2A,B). However, the true extent of fracture angulation can be underestimated on plain radiographs, as orthogonal views may fail to capture the true plane of angulation.
- Radial neck fractures can occur before the ossification of the radial head, without clear evidence of fracture on plain radiographs. Ultrasound, MRI (FIG 2C), and arthrography (FIG 2D,E) are useful for diagnosing and evaluating radial neck fractures in young patients with nonossified radial heads. In the operating room, arthrography is useful in outlining the nonossified radial head when monitoring and verifying reduction.

DIFFERENTIAL DIAGNOSIS

- The diagnosis of a radial neck fracture is usually easily made with appropriate imaging. However, the presence or absence of the following associated injuries should be ascertained:
  - Medial collateral ligament rupture
  - Medial epicondyle fracture
  - Olecranon fracture
  - Monteggia-equivalent type IV fracture

NONOPERATIVE MANAGEMENT

- Ultimately, the objective is to obtain and maintain a congruent joint with restored elbow range of motion in all planes. Most consider 30 degrees of angulation and 3 mm of translation an acceptable reduction. Controversy exists regarding the exact numbers, however, with reported acceptable angulation ranging from 20 to 60 degrees.\(^1,3,8,12,16,18,19,21,22\)
  - Two things partially account for the controversy:
    - The accuracy of the radiographic measurement is variable and depends on whether the radiographic beam is perpendicular to the true plane of the fracture.

FIG 2 • A,B. AP and lateral radiographs demonstrate an ulna fracture and radial neck fracture in a 3-year-old with a nonossified radial head. However, it is difficult to discern the degree of angulation on plain radiographs. MRI is useful when evaluating radial neck fractures in children with nonossified radial heads. C. The MRI from the same patient clearly shows the 60-degree radial neck angulation not defined on plain films. D,E. Arthrography demonstrates a 90-degree displaced radial neck fracture not seen on plain films. It is also useful to monitor and verify reduction intraoperatively.
Twenty-five degrees of fracture angulation can have variable effects on the congruity of the radioulnar joint, depending on the direction of angulation.

It is therefore important to base the decision of treatment on the functional effects of the angulation, rather than a specific number. Any block of pronation or supination warrants a reduction of the fracture, no matter what the radiographic angulation is.

As remodeling potential decreases with advancing skeletal maturity, less residual angulation is acceptable (15 to 20 degrees).\(^5,21\)

Closed reduction is recommended if there is more than 30 degrees of angulation or 3 mm of translation, or if there is any block to range of motion. Reduction can be done either with sedation in the emergency room or in the operating room. The advantage of the latter is the immediate ability to proceed to a percutaneous reduction technique should the closed techniques fail, which is more likely in cases with severe displacement.

The nature and duration of immobilization depend on the fracture pattern, the presumed stability, and the maturity of the patient. For example, a 17-year-old reliable patient with a nondisplaced stable radial neck fracture can be treated with a sling and early range of motion. Physeal fractures, fractures needing reduction, and fractures in young patients usually need immobilization in a cast for 3 weeks, however.

When clinical and radiographic signs of healing are lacking, the cast may remain for an additional 2 weeks, followed by a re-evaluation of the healing progress.

**SURGICAL MANAGEMENT**

If closed reduction fails, the next step is to proceed to a percutaneous reduction technique. Techniques using a Steinmann pin to push or lever are described in detail in the Techniques section.

Every attempt to achieve a closed or percutaneous reduction is made, as the rates of complications, including avascular necrosis, heterotopic ossification, and nonunion, are higher with an open approach.\(^3,12\)

The markedly displaced floating fragments associated with elbow dislocations often require an open approach, while most angulated radial head fractures can be reduced by a combination of closed and percutaneous techniques.

**Preoperative Planning**

It is essential to obtain proper elbow and forearm radiographs and diagnose all injuries before proceeding to the operating room.

Familiarity with all of the closed and percutaneous reduction techniques described in the Techniques section is useful, as each fracture behaves and responds differently to different techniques.

It is prudent to advise both the parents and the operating room staff that a range of techniques from closed to open may be employed to obtain reduction. Doing so eliminates any element of surprise. The surgeon should ensure the availability of elastic titanium nails, Kirschner wires, and Steinmann pins if needed.

Elbow range of motion and stability are assessed under anesthesia. The elbow is then pronated and supinated under fluoroscopy to find the maximum plane of angulation before reduction (FIG 3).

Several different techniques of closed and percutaneous reduction make up the “reduction ladder” covered in the Techniques section, much like the plastic surgeon’s reconstructive ladder. These tools may be used in stepwise progression or in conjunction as needed.

**Positioning**

The patient is positioned supine on the operating room table, with the elbow on the fluoroscopy C-arm and the arm positioned on the collimator of the C-arm (FIG 4).

The imaging monitor is placed at the opposite side of the bed for easy visualization.

**Approach**

The posterolateral Kocher approach is used for open reduction of severely displaced floating fragments. The approach is further described in the Techniques section.

---

**FIG 3** The maximal angle of displacement is found with fluoroscopy imaging through the ranges of full supination (A) to pronation (B). In this case, maximal angulation is noted with 50 degrees of pronation.
CLOSED REDUCTION

Israeli or Kaufman Technique

- Kaufman described a closed reduction technique with the elbow flexed 90 degrees.8
- Fluoroscopy is used to establish the forearm position demonstrating maximal angulation (see Fig 3).

One hand is used to control forearm rotation, and the other hand is used to provide lateral pressure to the displaced radial head with the thumb (TECH FIG 1A–C).
- After reduction, fracture stability and range of motion are assessed (TECH FIG 1D–G).

**TECH FIG 1 • A–C.** Kaufman (Israeli) technique. One hand grips the forearm distally to control supination and pronation (A), while the thumb of the other hand reduces the fragment in the plane of maximal reduction (B), milking the head from distal to proximal (C). D–G. After reduction has been obtained, the stability and range of motion (pronation–supination) are assessed in extension and 90 degrees of flexion.
Patterson Technique

- With the elbow extended and forearm supinated, varus stress is applied to the elbow by an assistant. The surgeon reduces the fragment with lateral digital pressure (TECH FIG 2).

- If closed reduction fails, a Kirschner wire or a Steinmann pin can be used to directly push or lever the radial head into anatomic position.

- The surgeon must beware of the posterior interosseous nerve coursing volar and distally over the radial head. The radial head can be protected by pronating the forearm and by using a posterolateral pin approach (TECH FIG 3).

- The forearm is rotated during fluoroscopic guidance so that the plane of maximal angulation is visualized.

- The blunt end of a larger Kirschner wire, 0.062 inch or larger, is percutaneously inserted through the skin distal to the fracture and just off the lateral border of the ulna (TECH FIG 4A,B) through a 2-mm incision.

- With fluoroscopic guidance, the pin is placed against the posterolateral aspect of the proximal fragment and the radial head is pushed into place (TECH FIG 4C,D).

- Axial traction and rotation of the forearm can dislodge an impacted fracture and assist in the reduction.

- Alternatively, the pin (or a Freer elevator) can be used as a lever. When doing so, the skin entry site of the pin must be placed more proximally, however, at the level of the fracture site (TECH FIG 5A).

- With the pin just through the skin, the pin is pulled distally (applying tension to the skin) to allow a retrograde approach to the fracture.

PERCUTANEOUS REDUCTION WITH A KIRSCHNER WIRE OR STEINMANN PIN

- Drawbacks of this technique include the need for an understanding assistant providing countertraction and varus stress, and the potential difficulty in palpating the radial head in this position.

TECH FIG 2 • Patterson technique. A. The assistant helps with positioning the elbow in extension, applying a varus force, while holding the forearm in supination. B,C. Digital pressure from the thumb is applied to the radial head to achieve reduction.

TECH FIG 3 • The posterior interosseous nerve moves volar and medial with pronation, moving it away from the working area during percutaneous or open treatment of radial head and neck fractures.
The deeper soft tissues are then pierced, the fracture site is entered (TECH FIG 5B), and the proximal fragment is levered proximally to correct the angulation while translation is corrected with simultaneous lateral digital pressure. During the levering maneuver, the tensioned skin relaxes, thus making the reduction easier (TECH FIG 5C).

If the skin instead were entered distally for the lever maneuver, however, the skin tension during the reduction maneuver would make the reduction substantially more difficult.

After percutaneous reduction, fracture stability in all planes is assessed. If unstable, pin fixation of the fragment is recommended.

Kocher’s posterolateral approach to the radial head is used. Pronating the forearm brings the posterior interosseous nerve further anteromedially, away from the surgical field.

A skin incision about 5 cm long is made, centered over the posterolateral aspect of the radial head (TECH FIG 6A). The interval between the anconeus (radial nerve) and the extensor carpi ulnaris (posterior interosseous nerve) is developed (TECH FIG 6B).

A longitudinal incision is made along the capsule, unless the capsule has not already been torn open by the injury causing trauma (TECH FIG 6C).

The proximal fragment is identified and reduced under direct visualization and fluoroscopic guidance. If the annular ligament has been injured it should be repaired.

Occasionally, the fracture is widely displaced anteromedially, necessitating further exposure before identification. In such a case, a more extensile approach is recommended, as well as a formal proximal identification of the radial nerve and posterior interosseous nerve.

If the fracture requires open reduction, internal fixation is recommended.

A recent retrospective review of radial neck nonunions noted that they were commonly associated with an early loss of fixation, related to either displacement or premature removal of pins.20

Options for internal fixation include pins placed obliquely though the radial head in an “ice-cream cone” pattern throughout the safe zone. Absorbable pins can also be used. Radial head fixation can be
achieved with epiphyseal–metaphyseal interrupted, circumferentially placed absorbable sutures. For skeletally mature children, headless screws or a T-plate in the safe zone can be used.

- Although seldom indicated, Leung and Tse described a lateral mini-plate buttress technique for the open physis. The plate is anchored distally in the radial neck with 2-mm screws and left unattached proximally, providing a buttress preventing lateral dislocation of the radial head.

- Transcapitellar pin fixation has been described, but it provides poor distal fixation and is associated with pin breakage at the radiocapitellar joint.

## PEARLS AND PITFALLS

### Indications
- The surgeon should have a discussion with the family and alert the operating room staff regarding the “reduction ladder” and the various techniques that may be employed.

### Operative technique
- Although percutaneous reduction can be a tedious and time-consuming procedure, open reduction should be avoided if at all possible.
- A mini-open approach using a Freer elevator as a shoehorn can sometimes reduce the fragment when percutaneous Steinmann pin reduction is unsuccessful.
- If an open reduction is necessary, fixation is necessary.
- Transarticular pins should be avoided as they break at the joint.
- Radial head excision is contraindicated in children because of valgus elbow deformity, longitudinal forearm instability, and high incidence of overgrowth.

### Imaging
- After achieving reduction, the surgeon should verify improved range of motion and make sure that the reduction is a true change in alignment and not simply a radiograph taken out of the plane with maximal angulation.
- The surgeon should beware of reversal of radial head position during radial head reductions and should make sure on plain radiographs that the radial head is properly reduced and not flipped 180 degrees.

### Follow-up
- Clinical or radiographic signs of fracture healing should be present before removing pin fixation. The period of pin fixation or immobilization should be longer for unstable, high-energy injuries.

## POSTOPERATIVE CARE
- After reduction, the elbow is immobilized in 90 degrees of flexion in the position of supination–pronation that is most stable for 3 weeks.
- If a splint is used postoperatively because of swelling, it is changed to a cast at 1 week.
- At follow-up, the cast is removed for radiographic and clinical examination. If healing is inadequate (which is more likely in higher-energy injuries in older children), the cast (and the pins if used) is continued for 2 more weeks, after which patient is re-evaluated for healing.

- If pin fixation is used, no elbow motion is allowed until pins are removed.
- Graduated range-of-motion exercises begin when the cast is removed.

## OUTCOMES
- Many series have shown a good to excellent outcome in 76% to 94% of children with radial neck fractures.
- Indicators for a favorable prognosis include younger age (less than 10 years), isolated low-energy injury, closed reduction, early treatment, less than 30 degrees of initial ang-
gulation, less than 3 mm of initial translation, and reduction within parameters discussed above.3,12,17

- Poor outcomes, such as limitations in range of motion, have been reported in 6% to 30% of patients, usually after a severely displaced radial neck fracture.

- Risk factors for a poor outcome include severe displacement, associated injuries, delayed treatment, poor reductions, old age, fractures needing open treatment and internal fixation, and intra-articular fractures in patients with an open physis.10,12,16,17,20

- Poor outcomes that have been noted with open procedures are partially due to a selection bias, where patients needing open procedures are more likely to have had high-energy injuries with additional vascular and soft tissue trauma.

**COMPLICATIONS**

- Loss of joint congruity, fibrous adhesions, and radial head overgrowth result in a loss of elbow motion. In order of decreasing frequency, pronation, supination, extension, and flexion are affected.15

- Radial head overgrowth is observed in 20% to 40% of cases due to presumed increased vascularity stimulating the physis. Premature physeal closure can occur and is seldom symptomatic, but it can accentuate a valgus deformity. Delayed appearance of the ossific nucleus is possible after a fracture occurring before ossification.

- Avascular necrosis of the radial head occurs in 10% to 20% of patients.3,12 Seventy percent of cases occur in cases of open reduction.3

- Radial neck nonunions are rare but have been reported and are often associated with premature loss of fixation.20

- Posttraumatic radioulnar synostosis occurs in 0% to 10% of cases,3,12,16 typically in association with open reductions, extensive dissection, residual displacement, and concurrent ulna fracture. Exostectomy of synostosis is a technically demanding procedure with a variable success rate.

- Heterotopic ossification (6% to 25% of cases)3,12 can occur as myositis ossificans in the supinator or as ossification within the capsule. Surgical treatment is rarely indicated.

**REFERENCES**

DEFINITION
- Radial neck fractures in children are typically transphyseal injuries and seldom involve the epiphysis (radial head).
- The majority of these fractures are Salter-Harris type II injuries. Salter-Harris type I fractures are also common. In older children some fractures may be entirely metaphyseal (FIG 1).
- Radial neck fractures represent about 14% of all elbow fractures in children.8

ANATOMY
- Ossification of the proximal radial epiphysis (radial head) occurs by 4 years of age, at which time the radial head and neck have assumed their adult shape. The proximal radial physis closes at 14 years in girls and 17 years in boys.
- At the level of the radiocapitellar joint, the radial nerve divides into its terminal branches, including the posterior interosseous nerve, which enters the substance of the supinator muscle at the arcade of Frohse and winds around the anterolateral aspect of the radial neck. Pronation of the forearm moves the posterior interosseous nerve more medially and away from the anterolateral side of the radial neck (FIG 2).

PATHOGENESIS
- The most common mechanism of injury is due to a fall on the outstretched hand with the elbow extended and the forearm supinated.
- The resultant valgus force compresses the capitellum against the radial head.

PATHOGENESIS
- Radial neck fractures may occur in association with a posterior dislocation of the elbow that displaces the radial head anteriorly.12
- A posteriorly displaced radial neck fracture can occur during the spontaneous reduction of a posterior elbow dislocation.4
- Alternatively, an unrecognized (undisplaced) radial neck fracture can be displaced posteriorly during the manipulative reduction of a posterior elbow dislocation. During the reduction maneuver, if the elbow is flexed, the distal humerus (lateral condyle) strikes the radial head, knocking it posteriorly off the metaphysis (FIG 3).

NATURAL HISTORY
- Most radial neck fractures are minimally displaced or undisplaced. These heal uneventfully.
- The greater the degree of angulation or translation, the greater the disruption in the relationship of the radiocapitellar joint, which may be associated with a decrease in the range of pronation and supination.2
- The upper limit of acceptable angulation (0 to 60 degrees) is unclear and may be age-dependent.16 Most believe that angulation less than 30 degrees is unlikely to cause a clinically (functionally) significant loss of motion.
Other reported consequences include avascular necrosis of the radial head, heterotopic ossification, radioulnar synostosis, and premature physeal closure, which may result in pain, crepitus, and valgus deformity and stiffness.\(^2,5,16,18,19\)

- These outcomes may be associated with age, severity of displacement, presence of associated injuries, or delay in treatment.
- Some of these might be a complication of the treatment (poor reduction, open treatment, or internal fixation) rather than the natural history.

**PATIENT HISTORY AND PHYSICAL FINDINGS**

- History of a fall on the outstretched hand
- Swelling of the elbow with limited range of motion associated with pain. Occasionally lateral ecchymosis may be evident.
- Tenderness and crepitus may be localizable to the radial head, provoked by gentle pronation and supination.
- The clinician should rule out an elbow dislocation and look for other areas of tenderness that might point to associated injuries.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Anteroposterior (AP) and lateral radiographs of the elbow. Oblique views can be helpful but are not routinely necessary.
- Amount of displacement: angulation and translation of the radial neck are noted.
- There are numerous classification systems of the severity of initial displacement. Most categorize the fractures based on amount of angulation,\(^2\) usually in 30-degree increments, while some also include translation.\(^6,9,16,18,19\)
  - The Judet classification is a simple descriptive system (FIG 4; Table 1).\(^6\)
  - The clinician should carefully rule out associated injuries such as fractures of the olecranon (intra-articular) (FIG 5), proximal ulna, medial epicondyle, or lateral condyle or elbow dislocation.
  - In posterior elbow dislocations, the clinician should carefully examine the radial neck for an occult fracture that is at risk for displacement during the reduction maneuver.
Differential Diagnosis

- Radial neck fractures
- Radial head fractures
- Monteggia variant: the clinician should look for any olecranon fractures or proximal ulna fractures
- Elbow dislocations

Nonoperative Management

- The Patterson reduction technique involves longitudinal traction applied to the extended arm with countertraction provided proximally.
  - The forearm is rotated (supinated) until the maximum tilt of the radial head is directed laterally.
  - A varus force is then applied to the elbow, while the radial head fragment is reduced by direct pressure.13
- Kaufman and associates’ describe a closed reduction maneuver with the elbow in 90 degrees of flexion and in maximum supination (the Israeli technique).
  - Thumb pressure is applied to the lateral aspect of the displaced radial head while the forearm is rotated gradually into full pronation.

Surgical Management

- Many displaced radial neck fractures can be satisfactorily reduced to an acceptable position with one of the above closed reduction techniques.
  - Failure to obtain or maintain an adequate closed reduction of Judet type 3 or 4 fractures (more than 30 degrees) is an indication for closed operative techniques.
  - Percutaneous leverage of the radial neck fracture using a Kirschner wire or Steinmann pin is one option.
  - Alternatively, reduction of the radial head can be accomplished by intramedullary manipulation of the radial head using a flexible or elastic nail or a Kirschner wire, with the nail or wire retained to stabilize the fracture if necessary.
  - Intramedullary reduction may be facilitated by the percutaneous leverage technique.
  - Open reduction with internal fixation is reserved for fractures that cannot be successfully managed by the above closed means.

Preoperative Planning

- Careful examination of the radiographs is necessary to rule out intra-articular involvement of the radial head as well as associated injuries of the proximal ulna and distal humerus (FIG 5).
  - The orientation of the displaced radial head must be confirmed to ensure that the articular surface of the fragment is not flipped 180 degrees.
  - A set of Kirschner wires or Steinmann pins should be available if percutaneous pin-assisted reduction using the joystick or leverage technique is considered necessary.
  - If flexible intramedullary nail-assisted reduction is being considered, the narrowest diameter of the intramedullary canal of the radius must be measured to select the appropriate diameter of the intramedullary nail or device (Kirschner wire or elastic titanium nail).
  - Under general anesthesia, closed reduction of the fracture is attempted under fluoroscopic guidance before the decision is made to proceed.

Positioning

- The patient is supine with the injured arm positioned over a radiolucent armboard.
- The image intensifier may be positioned parallel to the operating table to allow the C-arm to be moved freely from the AP to lateral position.

Approach

- For the percutaneous pin-assisted reduction technique, the pin or Kirschner wire is inserted from the posterolateral aspect of the radial neck with the forearm pronated to avoid injury to the posterior interosseous nerve.
  - For the centromedullary technique, the preferred entry point for the elastic nail is at the distal radius proximal to the growth plate through a 1.5-cm incision.
  - If the entry point is on the radial side, care is taken to avoid injury to the branches of the superficial radial nerve. The entry site is placed away from the tendons of the first extensor compartment.
  - An alternative entry point is the dorsal approach, just proximal to the tubercle of Lister, between the third and fourth extensor compartments.
  - If the elastic nail is being retained for fixation of the fracture, the radial approach is favored to prevent late rupture to the extensor pollicis longus tendon, which has been reported with the dorsal approach.
  - This complication can be avoided if the end of the retained nail is trimmed above the dorsal aspect of the extensor tendons so as not to abrade its volar surface.

**FIG 5**  A. Radial neck fracture with associated intra-articular fracture of the olecranon. Olecranon fracture appears minimally displaced on lateral view. B. Significant displacement is seen on AP view.
PERCUTANEOUS PIN (JOYSTICK) REDUCTION TECHNIQUE\textsuperscript{1,14,18}

Insertion and Manipulation of the Kirschner Wire

- Using the image intensifier, the Kirschner wire is inserted from the posterolateral aspect of the radial neck (TECH FIG 1A).
- During the insertion of the pin the forearm is best pronated to avoid injury to the posterior interosseous nerve. The surgeon should observe the thumb and index finger for any signs of metacarpophalangeal extension.
- Once the tip of the Kirschner wire has reached the fracture site, the forearm may be rotated until the maximum displacement of the radial head is visualized (TECH FIG 1B).
- The Kirschner wire is then advanced into the fracture site between the radial head (epiphysis) and the metaphysis and the fracture is disimpacted (TECH FIG 1C,D).
- The Kirschner wire is then swung cephalad to lever the radial head back into position (TECH FIG 1E–G).

TECH FIG 1 • A. Position of pin for percutaneous pin-assisted reduction of a displaced radial neck fracture. B–G. When the Kirschner wire has been introduced into the fracture site, it is used to lever the radial head fragment into position by swinging it cephalad.
**Use of Second Kirschner Wire**

- Occasionally the radial head remains translated even though the angulation has been corrected. With the first Kirschner wire in place, a second Kirschner wire may be introduced percutaneously to push the laterally translated fragment medially back into position (TECH FIG 2A–C).
- The Kirschner wire is removed and the stability of the reduction assessed.

- If the reduction is stable, as is usually the case, no internal fixation is required. The elbow is immobilized in 90 degrees of flexion with a posterior splint for 2 or 3 weeks.
- If the reduction is unstable, the Kirschner wire may be used to repeat the leverage technique and then advanced with a power driver obliquely through the metaphysis to act as a buttress to prevent the radial head from redisplacing.
- The Kirschner wire does not need to pass through the substance of the proximal fragment (TECH FIG 2D,E).

**CLOSED INTRAMEDULLARY REDUCTION AND FIXATION (METAIZEAU TECHNIQUE³)**

**Metaizeau Technique**

- Metaizeau described an intramedullary reduction and fixation technique for the treatment of displaced radial neck fractures⁹ that has been widely adopted.³,¹⁵,¹⁷
- The intramedullary manipulation of the radial head may be accomplished by an elastic titanium nail or a Kirschner wire of sufficient length, the tip of which is bent about 30 degrees.
- The diameter of the elastic nail or Kirschner wire is usually 2 mm. A 2.5-mm nail may be suitable in some children older than 10 years. The curved nail tip can be bent additionally.
- The preferred entry point for the nail is on the lateral cortex of the distal radius 1.5 to 2 cm proximal to the physis. It is created with a sharp awl or drill through a 1.5-cm incision, taking care to avoid injury to the sensory branch of the radial nerve (TECH FIG 3).
Chapter 7 PERCUTANEOUS JOYSTICK AND INTRAMEDULLARY REDUCTION (METAIZEAU) TECHNIQUES

Engaging the Fragment
- The elastic nail is attached to a T-handle and advanced proximally through the medullary canal under fluoroscopic guidance (TECH FIG 4A–C).
  - The forearm is rotated until the plane of maximum deformity is visualized.
  - The curved tip of the nail or the Kirschner wire is directed toward the displaced proximal fragment and gently advanced across the fracture until the tip engages the epiphyseal fragment without penetrating the articular surface (TECH FIG 4D–F).
  - AP and lateral radiographs are obtained to confirm the position of the nail tip in the epiphyseal fragment.

Rotating the Fragment into Place
- The nail tip is used to elevate the fragment to reduce the tilt anchoring the proximal fragment against the lateral condyle.
  - The T-handle is then used to rotate the nail or Kirschner wire typically anteriorly and medially, thereby reducing the lateral or posterolaterally displaced radial head back to its normal location (TECH FIG 5).
  - If the epiphysis is displaced anterolaterally, the nail is rotated posteriorly and medially.
  - The intact periosteum prevents overcorrection of the fragment medially.

Completing the Procedure
- The reduction maneuver may be facilitated with a prior or concurrent closed reduction. In severely displaced radial neck fractures, the percutaneous technique described above may be performed concurrently to facilitate the intramedullary reduction (TECH FIG 6A).
  - With the nail tip engaged in the epiphysis and the reduction complete, the stability of the fracture is assessed and the nail is left in situ.
  - The nail is trimmed 1 cm proud of the bone at the entry site (TECH FIG 6B).
  - If the dorsal approach is used, the nail can be bent 90 degrees dorsally and trimmed just above the plane of the extensor pollicis longus tendon to ensure that the end of the nail does not abrade the tendon (TECH FIG 6C).
**TECH FIG 4** • Closed intramedullary reduction and fixation technique of Metaizeau with an elastic nail. **A–C.** Proximal advancement of elastic nail through the medullary canal. **D–F.** The curved tip is directed toward and advanced into the displaced epiphyseal fragment.

**TECH FIG 5** • The elastic nail is rotated anteriorly and medially to reduce the radial head.
**POSTOPERATIVE CARE**
- A short period of immobilization may be necessary, but usually active range of motion can be started after 2 to 3 weeks. If the fracture is stable or stabilized by the elastic nail, the arm can be placed in a sling and gentle active range of motion encouraged as soon as tolerated.
- Early passive range of motion is not recommended because of the risk of heterotopic ossification.
- The elastic nail or Kirschner wire is removed after 6 to 8 weeks, when the fracture has healed clinically and radiographically.

**OUTCOMES**
- A good outcome, defined as a functional painless range of motion without complications, can be expected in 78% to 93% of Judet grade 3 or 4 fractures treated by elastic stable intramedullary nailing.\(^5,15,17\)

**COMPlications**
- Posterior interosseous nerve injury\(^15\)
- Injury to sensory branch of radial nerve
- Late extensor pollicis longus rupture
- Penetration of the articular surface of the epiphysis, requiring early removal (FIG 6A)
- Malreduction of the radial head flipped 180 degrees\(^11\) (FIG 6B–E)
- Loss of reduction can be avoided by checking stability intraoperatively or retaining the Kirschner wire or elastic nail for fixation.
- Minor limitation of motion
- Avascular necrosis
- Radial head overgrowth
- Premature physeal closure is common as a consequence of the injury, treatment, or both. The clinical significance of this is unknown but it is unlikely to be problematic.
- Nonunion\(^21\)
- Radioulnar synostosis
- Periarticular heterotopic ossification

### TECH FIG 6
- A. Intramedullary reduction can be facilitated by concurrent percutaneous pin reduction technique.
- B. The end of the nail is left proud off the entry site to facilitate removal. C. If a dorsal entry point is used, the end of the nail is trimmed above the level of the tendons to prevent rupture.
TRAUMA

Pin-assisted reduction. D. Apparent anatomic reduction. E. AP view reveals radial head fragment is flipped over 180 degrees.

REFERENCES

DEFINITION
- Cubitus varus is a deformity of the distal humerus that results in a change in the carrying angle from physiologic valgus alignment between the upper arm and forearm.
- Historically, cubitus varus was the most common complication following supracondylar humerus fracture, with a frequency as high as 30%.
- The appearance of the deformity is the major concern for the parents and patient, as there is little functional deficit.

ANATOMY
- Bone
  - The distal humerus consists of two structural columns of bone medially and laterally.
  - The olecranon and coronoid fossae separate the two structural columns.
  - The cortices of the distal humerus are thinner in the child than the adult, and the anteroposterior (AP) diameter of the distal humerus is decreased in children.
- Neurovascular
  - The median nerve and brachial artery run along the medial border of the biceps brachii muscle in the upper arm and come to lie anterior and slightly medial in the cubital fossa.
  - The radial nerve enters the anterior compartment of the arm in the distal third of the upper arm and travels between the brachialis and brachioradialis over the anterolateral distal humerus before it enters the supinator muscle in the proximal forearm.

PATHOGENESIS
- Cubitus varus occurs because of a malunited supracondylar humerus fracture and is not due to a growth disturbance of the distal humerus epiphysis.
- The primary cause is coronal varus angulation of the distal humeral metaphysis.
- Varus angulation can be caused by medial column comminution, causing the fracture to collapse into varus. Varus angulation can rarely be caused by lateral gaping at the fracture site.
- Other coexisting deformities can exist with cubitus varus, including extension and internal rotation of the distal fragment.

NATURAL HISTORY
- The deformity is static and does not evolve with time.
- The deformity is often not appreciated until several months after the fracture heals and the elbow flexion contracture that results from casting resolves.
- Tardy ulnar nerve palsy may occur owing to compression by chronic malpositioning of the triceps muscle due to a shift of the olecranon in the olecranon fossa.
- There may be a slight increased risk of subsequent lateral condyle fractures in children with cubitus varus.

PATIENT HISTORY AND PHYSICAL FINDINGS
- A detailed history is essential to understand parental and patient expectations of treatment in cubitus varus.
- Physical findings include a varus change in the carrying angle when compared to the opposite, unaffected side.
- Elbow and forearm range of motion should be documented.
- A thorough examination of nerve function to the forearm and hand should be performed.
- Hyperextension of the elbow indicates coexisting extension deformity at the malunion site.
- A loss of external rotation can be due to shoulder pathology or due to an internal rotation malunion at the distal humerus.
- The difference in carrying angle between the affected and unaffected side is the amount of cubitus varus.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- Plain AP and lateral radiographs of the affected elbow should be obtained (FIG 1).
- Additionally, an AP radiograph of the affected and unaffected elbow in full extension and supination that includes the distal humerus, forearm, and wrist should be obtained. This is used to plan the amount of surgical correction desired.
- Advanced imaging (MRI of the elbow) may be of value in young children where distal humeral growth disturbance is suspected.

DIFFERENTIAL DIAGNOSIS
- Medial humeral condylar or trochlear growth disturbance
- Malunited lateral humeral condyle fracture
- Congenital dislocation of the radial head
- Malunited fracture/separation of the distal humeral physe

NONOPERATIVE MANAGEMENT
- Nonoperative management does not affect the appearance of cubitus varus.
- If correction is contemplated, surgery should be undertaken at least 1 year after injury to ensure that there is no evidence of distal humeral avascular necrosis.

SURGICAL MANAGEMENT
- Surgical indications
  - Skeletally immature child with posttraumatic cubitus varus
  - Full elbow extension and flexion to at least 130 degrees
  - Child and family unaccepting of the appearance of the elbow
  - At least 1 year after initial injury
- Surgical goals
  - Correction of the carrying angle to equal the contralateral side
In our experience, rotational deformity is well compensated for by shoulder and forearm rotation and does not need to be addressed surgically.

Preoperative Planning

- Preoperative AP radiographs of both elbows should be taken in full extension and supination.
- The angle of Bauman and the humeral-elbow-wrist angle should be determined for both sides.
- A tracing of the normal arm on tracing paper is reversed and superimposed on the radiograph of the operative arm (FIG 2A–C).
- By adding the humeral-elbow-wrist angles, the amount of planned correction can be estimated (FIG 2D). Alternatively, attempting to match the Bauman’s angle of the contralateral side can help estimate the amount of correction needed.
- The distal osteotomy cut is just proximal to the olecranon fossa.
- The osteotomy is planned with equal lengths of the proximal and distal limbs; this diminishes the tendency for a lateral condylar prominence.
- The angle of the wedge to be removed is the same as the angle of desired correction.
- Because the osteotomy is performed proximal to the deformity apex and hinges medially, there is a lateral shift of the forearm axis that will make the lateral condyle more prominent than in the normal arm, even with equal osteotomy limbs.
  - This appearance is more accentuated in patients with neutral humeral-elbow-wrist angles.
  - In these cases, a complete osteotomy with medial translation of the distal fragment should be planned.

Positioning

- The patient is placed supine with the arm on a radiolucent extremity table. A sterile upper arm tourniquet is used; this facilitates complete intraoperative visualization of the upper arm.
The lateral approach to the distal humerus is used, between the lateral head of the triceps muscle and the extensor carpi radialis longus muscles (TECH FIG 1A). A posterior approach can be used as well, if cosmesis is of paramount importance; however, the lateral approach is technically simpler. The distal humerus is subperiosteally exposed both anteriorly and posteriorly, and small Hohmann retractors are placed (TECH FIG 1B).

EXPOSURE

- The proximal and distal osteotomy cuts are made with a small oscillating saw as per the preoperative template. Kirschner wires inserted under image intensification can be used to mark the osteotomy sites.
- The distal osteotomy is performed proximal to the olecranon fossa. The proximal osteotomy meets the distal osteotomy at the medial cortex, leaving it intact.
- With the elbow extended, a valgus force is placed on the elbow, closing the osteotomy by creating a greenstick fracture at the medial cortex.
- A single distal lateral-to-proximal medial Kirschner wire is placed percutaneously (not through the incision) to hold the osteotomy apposed.
- The osteotomy site is tested for stability with real-time fluoroscopy. If the osteotomy is unstable, a second distal medial-to-proximal lateral Kirschner wire is used to supplement fixation (TECH FIG 2).
- If there is a lateral condylar prominence after performing the greenstick osteotomy, the Kirschner wire is removed, the medial cortex is cut, and the distal fragment is translated medially to remove the prominence. In this situation, routine medial and lateral Kirschner wire fixation is used.
- The medial Kirschner wire is inserted with the elbow relatively extended.
- The thumb is used to hold the ulnar nerve posterior to the medial epicondyle within the cubital tunnel.
- A small skin incision is made over the medial epicondyle, and a hemostat is used to spread the subcutaneous tissue to the underlying bone.
- Care is taken to prevent the wires from crossing at the osteotomy site.
- Fixation is evaluated with biplanar fluoroscopy to ensure proper pin placement before wound closure.
POSTOPERATIVE CARE
- With the technique described, patients are immobilized in a long-arm cast for 4 to 6 weeks. When radiographs show callus formation at the osteotomy site, the percutaneous Kirschner pins can be removed (FIG 3).

- The patient is then given a sling and active range-of-motion exercises are initiated.
- Once radiographic union is achieved, the sling is discontinued, and the patient can begin full activities once range of motion is restored.

WOUND CLOSURE
- The wound is irrigated and closed in layers in the standard fashion.
- The Kirschner wires are left protruding from the skin and are bent to prevent migration of the pins underneath the skin.
- A long-arm cast or splint is applied with the elbow in 90 degrees of flexion and the forearm in slight pronation. The patient should be closely monitored in the early postoperative period for swelling.
- If a splint is used, it is converted to a long-arm cast after swelling has subsided.

PEARLS AND PITFALLS

OUTCOMES
- Patient outcomes after supracondylar humeral osteotomy are good to excellent in most cases, with retention of range of motion and improved appearance of the elbow as the major outcome measures.
- Loss of fixation, persistent lateral condyle prominence or undercorrection, and hypertrophic scar negatively impact outcome.6

COMPLICATIONS
- Persistent lateral condylar prominence6
- Nonunion
- Refracture6
- Hypertrophic lateral scar6
- Loss of fixation2
- Recurrent deformity
- Radial or ulnar nerve palsy
- Infection

REFERENCES
DEFINITION
- Commonly seen fractures include proximal humerus fractures (physseal and metaphyseal) and clavicle fractures and dislocations, as well as less commonly seen fractures of the scapula.
- Most of these injuries can be treated nonoperatively because of the significant remodeling potential.
- Certain fractures will require operative treatment, however, due to decreased remodeling capacity in the older child (proximal humerus), risk to surrounding structures (sternoclavicular dislocations), and open or threatened skin (clavicle fractures).
- Acromioclavicular joint injuries are often physeal fractures in the growing child and are almost exclusively so in children younger than 16 years old. The ligaments usually remain attached to the thick clavicular periosteum, and are thus usually intact.
- Opinion varies on the need for surgical repair, although most do well treated nonoperatively.\(^1,6\)
- Aggressive surgical treatment for some of these injuries (clavicle fractures, scapular fractures) is rarely indicated for most children. Operative treatment in these cases is the same as for the adult patient and will be covered in other chapters in this book.

ANATOMY
- The proximal humeral physis is responsible for 80% of humeral growth. It remains open usually until age 14 to 17 in girls, age 18 in boys.
  - A major portion of the physis is extracapsular and vulnerable to injury.
  - The anterior periosteum is usually thinner than the posterior, often leading to hinging of the fragments posteriorly and possible entrapment of the periosteum anteriorly.
  - The proximal humerus lies in close proximity to the brachial plexus and axillary vessels. Care should be taken to document function of the innervated musculature before initiating treatment (FIG 1).
  - The medial clavicular epiphysis is the last in the body to appear (age 18 to 20 years) and the physis is the last to close (age 23 to 25 years).
  - This is why most of these injuries are physeal fractures rather than true dislocations.\(^2\)
  - Immediately posterior to the sternoclavicular joint lie the trachea, esophagus, and great vessels.

PATHOGENESIS
- Injuries to the proximal humerus occur from either a direct blow to the region or indirect trauma, such as a fall onto the outstretched hand.
  - In cases of pathologic fractures through bone cysts, throwing a ball or reaching overhead can precipitate an injury.
  - Sternoclavicular injuries are usually caused by a direct blow to the clavicle, or by a blow to the lateral shoulder girdle that dislocates the clavicle anteriorly or posteriorly.
  - Scapular fractures are high-energy injuries, requiring comprehensive evaluation as per Advanced Trauma Life Support protocols.

NATURAL HISTORY
- Because of the significant remodeling potential in young children, most patients will heal without sequelae from fractures of the proximal humerus or clavicle.
- Intra-articular fractures of the glenoid should be treated as in the adult.
- Morbidity from associated injuries, however, may be significant, and thus a thorough evaluation is of paramount importance. Posterior sternoclavicular dislocations in particular threaten the great vessels, trachea, and esophagus.
- Debate exists as to the natural history of distal clavicle fractures with significant displacement, but most agree that conservative treatment is effective.\(^2\)
- General guidelines are available to define acceptable healing alignment for proximal humeral fractures (Table 1).

Examples of complete or near-complete remodeling are readily found in the literature for even completely displaced fractures in children less than 15 years old, however, so a clear understanding of the goals of the procedure and its associated risks is crucial.1,5

PATIENT HISTORY AND PHYSICAL FINDINGS

- History should include mechanism of injury, antecedent pain, and neurologic symptoms in the hand and arm.
- A high-energy injury should also prompt a full trauma workup using standard Advanced Trauma Life Support protocols.
- Physical examination begins with a thorough assessment of the skin for areas of compromise, particularly in clavicle fractures.
- Swelling from a sternoclavicular dislocation may mask initial displacement, so this area should be palpated for pain or crepitance. Stridor in the setting of a sternoclavicular injury is particularly worrisome.
- A neurologic examination to include the brachial plexus distribution, as well as a vascular examination of the arm, is necessary.
- Neurologic injury in conjunction with fracture may signify ongoing compression (ie, sternoclavicular dislocation) and may affect prognosis.
- A high suspicion for vascular injury is important in preventing late sequelae.

The clinician should palpate the medial and lateral clavicles and the proximal humerus to differentiate fracture from soft tissue injury.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Standard initial views of the shoulder should include a true anteroposterior (AP) view, a “shoot-through” lateral, and an axillary lateral view (FIG 2A,B).
- The “serendipity view” is helpful in cases of medial clavicle fracture or dislocation. This is taken by obtaining an AP radiograph of both clavicles with the beam angled 40 degrees cephalad (FIG 2C).
- Computed tomography can be helpful to assess cases of suspected sternoclavicular dislocation, as a contrast study will provide information about potential vascular injury (FIG 2D), as well as detail the relationship of the clavicle to the trachea and esophagus (FIG 2E).
- CT is the standard, although some have recommended MRI.4

DIFFERENTIAL DIAGNOSIS

- Proximal humerus metaphyseal fracture
- Proximal humerus physeal injury
- Shoulder dislocation
- Acromioclavicular fracture-dislocation
- Sternoclavicular fracture-dislocation
- Child abuse

FIG 2 • A,B. Preoperative AP and lateral radiographs of a Salter-Harris type II fracture of the proximal humerus in a 15-year-old girl show mild valgus angulation and complete displacement with 90 degrees of angulation on the lateral view. C. In a different patient, apical oblique radiograph taken with fluoroscopy before reduction of a posterior sternoclavicular dislocation. Note the asymmetric heights of the inferior clavicles (*). D. In another patient, three-dimensional contrast-enhanced computed tomography image of left posterior sternoclavicular dislocation. Note the relationship to the great vessels. E. Axial view of the same patient as in D, demonstrating the injury to be a physeal fracture. The epiphysis (arrow) remains in place, while the metaphysis (*) is posteriorly displaced, immediately anterior to the vasculature.
NONOPERATIVE MANAGEMENT
- Most of these injuries can be treated nonoperatively.
- For proximal humeral fractures with acceptable alignment, treatment consists of sling management for comfort for several weeks, followed by a home range-of-motion program and return to activities in 6 to 8 weeks.
- Treatment of clavicle fractures consists of a sling for initial comfort, followed by a figure 8 bandage or sling, depending on the patient’s preference.
  - Immobilization can usually be discontinued after 3 weeks, with return to sports by 6 to 8 weeks.
  - While surgical management of distal clavicular physeal injuries has been advocated by some, the majority of patients do well with treatment similar to clavicular shaft fractures.
  - Older children can be treated as adults, and the surgical treatment of these injuries is discussed elsewhere.

SURGICAL MANAGEMENT
- The operative management of clavicle fractures and dislocations is well covered elsewhere in this text. Operative treatment of proximal humeral fractures will subsequently be discussed, as well as reduction of posteriorly displaced fracture-dislocations of the sternoclavicular joint.
- For physeal or metaphyseal fractures of the proximal humerus, operative treatment should be considered for fractures with unacceptable residual displacement.
- Closed reduction is often unstable and fixation is desirable.
- Because of open growth plates, standard plate-fixation techniques are rarely indicated.
- Threaded-wire fixation provides sufficient temporary fixation to allow healing.
- Failure to obtain a satisfactory closed reduction may require an open reduction, and surgeons should be familiar with this technique as well.
- Interposition of the biceps tendon has been noted to be the most common cause of a failed closed reduction,³ but other authors disagree.⁵

Preoperative Planning
- Good-quality radiographs of the shoulder should be available.
- It is important to rule out concomitant glenoid fracture or dislocation before surgery.

Positioning

Proximal Humerus Fractures
- For proximal humeral fractures, the patient is positioned in a modified beach-chair position, with the back elevated roughly 30 degrees.
- The imaging machine is then brought in from the head of the table. It can be tilted “over the top” to get an AP view and rotated to get an axillary lateral view (FIG 3).
  - If the table is too upright, the AP view may be difficult to obtain because of limited excursion of the C-arm past neutral.
- A vacuum positioning device (beanbag) is positioned under the patient’s head, neck, and upper torso. This allows the patient to be slid slightly over the edge of the table to allow full access to the shoulder girdle.
- A chest pad attached to the table prevents the patient from being pulled off the table inadvertently when traction is applied to the arm.
  - Alternately, a sheet can be wrapped around the torso and secured by an assistant on the opposite side of the table.

Sternoclavicular Dislocation
- Patients with posterior sternoclavicular dislocations should be positioned supine with a roll between their shoulders to allow hyperextension of the shoulder girdle. It is helpful to position the patient with the operative side near the edge of the table.

FIG 3 • Intraoperative positioning for reduction. A. The patient is over the edge of the table with the entire arm exposed. The imaging machine is brought in from the head of the table. It is tilted into the “over-the-top” position to obtain a true AP view of the shoulder. Note the surgeon’s hands; traction is applied with the left hand, while the right helps to correct the adduction of the distal shaft fragment. B. Without moving the arm, the image can be rotated to obtain an axillary lateral view. In this simulated figure, the fluoroscopy unit is not draped for clarity; in practice, it is brought up beneath the drapes to maintain the sterile field. The surgeon is applying pressure to reduce the apex anterior angulation, while maintaining traction with the left hand. Under the drapes, a chest pad prevents the patient from being pulled off the table with traction; a sheet wrapped around the torso and held by an assistant would accomplish the same purpose.
Approach

Proximal Humeral Fractures
- Reduction of proximal humeral fractures is, generally speaking, a closed procedure.
- Interposed tissue may require an open approach, which is through the deltopectoral interval (FIG 4).

Sternoclavicular Joint
- Reduction of sternoclavicular dislocations can also be performed in a closed fashion and treated without surgical repair of the ligaments.
- While I have treated these injuries with closed reduction followed by a figure 8 splint, close follow-up and postreduction CT are required to detect loss of reduction.

Because of this, others have recommended primary repair of all of these injuries.8
- Open reduction of these injuries is performed using a transverse incision overlying the sternoclavicular joint. A pediatric thoracic–vascular surgeon should be on standby, preferably in the room, because of the proximity of several vital structures in this region.
- The incision is carried through the platysma muscle down to the clavicular periosteum, which is elevated to expose the clavicle.
- Dissection is limited to within the periosteum to avoid injury to surrounding structures.
PROXIMAL HUMERUS FRACTURE

Closed Reduction

- To reduce the fracture, the forces acting on the humerus need to be understood. The proximal fragment tends to be abducted and externally rotated due to the pull of the rotator cuff musculature, while the shaft is adducted from the pull of the pectoralis major muscle. To correct this, the first step is usually abduction and external rotation of the arm.
- Traction is then applied to disengage the fragments. It is helpful to have an assistant stabilize the torso.
- Usually, the shaft can be manipulated in line with the head at this point.
  - The typical angulation to be corrected is varus and apex anterior angulation.
  - It is often helpful to think about pushing down on the proximal end of the shaft to correct the angulation while maintaining abduction to correct the varus.
- In smaller, thin patients it is possible to grasp the head through the axilla to assist with the reduction.
- Once reduced, stabilization ensues (see below).

Open Reduction

- In rare cases, a closed reduction cannot be successfully achieved. A common cause is entrapment of periosteum or biceps tendon.
- In these cases, a small deltopectoral incision can be made.
  - This is a limited approach, not the wide extensile exposure needed for open reduction and internal fixation.
  - A finger can usually be inserted through a small opening to allow clearance of obstructing soft tissue.
- Fixation then ensues (see below).

Percutaneous Pin Fixation

- Once reduced, the fracture is then stabilized.
- Threaded-tip pins, such as the 2.5-mm guide pins found in most cannulated hip screw systems, are ideal for pediatric use and are my first choice, although they are potentially unsuitable for use in osteoporotic adult bone. Fully threaded pins can also be used.
- It is important to understand the relationship of the important neurologic structures to the proximal humerus.
  - The axillary nerve lies in the deltoid muscle 5 cm (in an adult, less in a child) from the tip of the acromion laterally.
  - More anteriorly, the musculocutaneous nerve is at risk.
- Pins are placed through small stab incisions using a tissue protection sleeve after a hemostat has been used to spread the tissue down to the bone.
- Often the reduction is stable enough to allow the arm to be placed down at the patient’s side and internally rotated, which is the position of postoperative immobilization.
  - If not, the pin can be inserted in the abducted position, but on moving the arm down, the skin will then be tented by the pin.
- A relaxing incision can be made, or the first pin put in provisionally, the arm moved to the patient’s side, and the first pin removed after additional fixation has been obtained.
- The easiest pin to place first is usually from distal lateral to proximal medial (TECH FIG 1A).
- The pin is started perpendicular to the shaft, and the surgeon’s hand is then dropped to the correct angle.

**TECH FIG 1** Pinning of a proximal humeral fracture in the patient in Figure 2A,B with a Salter-Harris type II humeral fracture. A. After reduction, the first pin is placed. B. A second pin is then placed, starting more anteriorly and proximally. C. The pins are placed in a divergent fashion. The stab incisions (not shown) should be well distal to the pin–bone interface to prevent soft tissue tension. D. An “advance–withdrawal” test is performed under live fluoroscopy to confirm stability as well as the extra-articular nature of the pins.
It is important to make the initial approach down to the bone along the final angle of pin insertion to avoid skin tension problems later.

The pin is advanced into the head, stopping several millimeters below the subchondral bone.

A second pin is then added (TECH FIG 1B).

I usually prefer to place this pin starting more proximally and anteriorly to the first pin.

If the first pin is aimed at the inferior portion of the head, the second can be aimed more superiorly for greater pin divergence across the fracture (TECH FIG 1C).

If needed, a third pin can be added from the greater tuberosity downward into the shaft.

This is helpful in small patients for better purchase in the head, but I usually avoid this pin because of a higher rate of soft tissue complications.

After fixation is complete, an “advance–withdrawal” test is performed (TECH FIG 1D), similar to that done for a slipped capital femoral epiphysis.

The shoulder is rotated and the tips of the pins should appear to approach the joint surface and then withdraw with continued rotation.

Pins that appear too long should be pulled back.

In larger patients near or at skeletal maturity with sufficient bone stock, cannulated screws can be inserted over a wire in the same fashion as described for threaded pins.

I have found this technique rarely necessary, but it does avoid the issue of pin management (see below).

### POSTERIOR STERNOCLEAVICULAR FRACTURE-DISLOCATIONS

#### Closed Reduction

- My preferred initial technique is to attempt a closed reduction of these injuries. This is usually successful only if performed within 48 hours of injury.
- With a sandbag or towel roll placed between the shoulder blades, the patient is placed supine with the involved side close to the edge of the operating table.
- Intravenous anesthesia or conscious sedation may be used, but I prefer to perform the reduction under general anesthesia, both for patient comfort and so I can proceed to open reduction if required.
- Longitudinal traction on the ipsilateral arm is applied by an assistant.
  - The shoulder is then gradually extended.
  - This often will reduce the dislocation.
- If unsuccessful, the clavicle can be grasped and pulled upward, especially in thin patients.
- Finally, the region can be prepared and draped and a towel clip used percutaneously to grasp the clavicle and reduce it.
- The reduction is usually marked by a satisfying clunk and is often stable. This is not always the case, however, and the stability should be carefully confirmed.
- Gentle posterior pressure on the clavicle confirms the stability of the reduction.
- The shoulder is taken through a range of motion and the reduction checked as well.
- Finally, intraoperative fluoroscopy is used to confirm symmetry of the sternoclavicular joints.
- If confidence in a stable reduction exists, the patient is awakened and a postoperative CT scan obtained to assess the reduction (TECH FIG 2).
- Reductions of questionable stability require an open reduction.

#### Open Reduction

- The first step in this procedure is ensuring the presence of a pediatric vascular-thoracic surgeon in proximity to the operating room, preferably in the room.
- The medial clavicle is approached through a transverse incision centered on the sternoclavicular joint (TECH FIG 3A).
- The platysma muscle is divided and the clavicle periosteum exposed.
- It is helpful to come down on the clavicle laterally away from the injury. The periosteum can then be elevated medially, toward the injury.
- This allows careful exposure of the medial fracture (in the case of a true dislocation) or the physeal fracture site (in the case of a fracture-dislocation).
- The epiphysis lies laterally to the intra-articular disc ligament. Care should be taken when exposing this area so that dissection does not inadvertently excise the epiphysis.
- The medial clavicle is grasped with a pointed tenaculum and reduced (TECH FIG 3B).
- Although descriptions exist of temporary plating or pinning, the risks of these fixation techniques (migration of Kirschner wires, need for plate removal) do not justify
their use. Suture fixation can be performed simply with good results.4,8

- For true dislocations, 1- to 2-mm holes are made in the medial clavicle and the sternum (TECH FIG 3C).
- I use a burr for better control.
- There should be a generous bone bridge between the holes.
- An absorbable, braided no. 1 suture (as opposed to wire often used in adults) is passed through the drill holes in a figure 8 fashion and tied securely.
- For fracture-dislocations, the same technique is applied, but the medial holes are placed in the metaphyseal fragment (TECH FIG 3D).

> It is occasionally easier to pass two separate sutures in these cases.
> The needle is passed through one drill hole, out across the fracture site, and up through the hole in the corresponding fragment.
> This is repeated, and both sutures are subsequently tied.
> The periosteum is then repaired.
> After fixation, the reduction is tested for stability, and after confirmation of such, the wound is closed using standard technique.

**TECH FIG 3** • Approach for open reduction of a posterior sternoclavicular injury. A. The incision is centered on the joint, in line with the clavicle. Under the subcutaneous tissue lies the platysma muscle, which is also split in line with the incision. B. The clavicle is exposed subperiosteally, beginning laterally and working medially toward the joint. It can then be grasped with a towel clip and reduced. It is crucial to remain subperiosteal with the clip to avoid inadvertent injury to the vessels lying immediately posteriorly. After reduction, fixation is achieved with sutures. C. For a pure dislocation, a figure 8 pattern through burr holes will secure the joint. D. For a fracture-dislocation, it is often easier to use two separate sutures perpendicular to the fracture line.

### PEARLS AND PITFALLS

**Proximal humerus**

**Reduction**
- The arm should be fully abducted to allow reduction of the shaft onto the head. Gapping at the fracture may signify interposed tissue, and the preparation should allow open exposure if required.

**Pinning**
- The surgeon should avoid placing the pins in the region of the axillary and musculocutaneous nerve. The skin should be handled carefully and multiple punctures avoided to minimize soft tissue complications.

**Indications**
- A large remodeling potential exists. The surgeon should carefully consider patient age and remodeling capacity before proceeding with surgery. The surgeon should accept less-than-perfect reduction in lieu of open reduction if possible to avoid the complications associated with an open approach.

**Sternoclavicular joint**

**Closed reduction**
- The surgeon should consider open reduction and stabilization if doubt exists about stability.

**Open reduction**
- Preoperative imaging can identify potential associated injuries. A vascular surgeon should be available.
regardless of the treatment method chosen. Most patients with proximal humeral fractures will do well regardless of the treatment method chosen.

POSTOPERATIVE CARE

Proximal Humeral Fractures

- Aftercare of the pins is controversial. I prefer to leave the pins out of the skin for removal in the office.
  - This is usually easily accomplished at 3 to 4 weeks, when the fracture has gained sufficient stability from healing (FIG 5).
  - A battery-powered hand drill is helpful for securely grasping the pins and backing them out, as the tips are threaded.
  - The pins are wrapped in iodine-soaked gauze and covered.
  - They can be checked and redressed if concern exists, and pin care with half-strength peroxide is helpful.
- In obese patients, or in young patients who may have difficulty with activity restriction in the sling, soft tissue movement around the pins may lead to infection.
  - In these patients, the pins should be cut beneath the skin.
  - Removal then requires an additional trip to the operating room, usually at 4 to 6 weeks after surgery.
- After pin removal, the patients are instructed to begin gentle active-assisted shoulder range of motion.
  - Once healing is complete radiographically, formal physical therapy can be initiated to gain any additional mobility and strength.
  - Most children do well, however, by gradually resuming activities at their own pace.

Sternoclavicular Joint Injuries

- After postreduction CT confirms reduction, the patient is followed at weekly intervals for the first 3 weeks with apical oblique radiographs.
  - Immobilization in a figure 8 harness is continued for 6 weeks.
  - Return to sports is allowed at 3 months.
  - Open reductions are protected for 4 to 6 weeks in sling and swathe.
  - Gentle range of motion is begun at 4 weeks.
  - Again, sports participation is restricted for 3 months.

COMPICATIONS

- Proximal humerus fractures
  - Nerve injury
  - Pin tract infection or osteomyelitis
  - Persistent stiffness
  - Growth disturbance
  - Fracture through pin hole in cortex
- Sternoclavicular injury
  - Infection
  - Neurovascular injury
  - Persistent subluxation

OUTCOMES

Proximal Humerus

- Most patients with proximal humeral fractures will do well regardless of the treatment method chosen.

Younger patients, particularly less than 15 years of age, will do well with closed treatment in the absence of neurovascular injury or open fracture.

Operative treatment usually results in satisfactory healing, although several reports note a high rate of complications from operative treatment, including late fracture through a pin hole and late osteomyelitis.1

Sternoclavicular Joint

- Patients who undergo closed reduction of posterior sternoclavicular joint fracture-dislocations can be expected to do well.
  - Some authors recommend accepting residual displacement unless the patient has symptoms of mediastinal compression, as remodeling of the fracture can be expected; however, that view is not universal.10
  - Some authors believe that closed reduction is not sufficiently stable and report excellent functional outcomes from open reduction.5
  - Anterior sternoclavicular joint injuries, after reduction, are usually unstable.
  - The outcome in these injuries is usually quite good, as remodeling will occur and there is no risk to mediastinal structures.2

REFERENCES

FIG 5 • Radiograph taken 4 weeks after surgery of the patient in Techniques Figure 1, before pin removal. Medial sclerosis indicates healing.
DEFINITION
- Hip fractures in children may be intra-articular, involving the physis or femoral neck, or extra-articular, involving the intertrochanteric or subtrochanteric regions.

ANATOMY
- The femoral head is composed of the capital femoral epiphysis, the subcapital physis, and the most proximal portion of the femoral neck (FIG 1A,B).
- The femoral neck forms an angle of about 135 degrees with the femoral shaft. The medial two thirds of the neck is intracapsular; the lateral third is not.
  - The important retinacular vessels that supply the capital femoral epiphysis course along the femoral neck.
  - The intra-articular femoral neck has little if any periosteum.
- The lesser trochanter is an apophysis in the child and forms the insertion for the iliopsoas.
- Much of the greater trochanter is apophyseal and forms the insertion for the hip abductors.
- Fractures may occur through the growth plate (transphyseal), in the intracapsular femoral neck, or in the region distal to the capsule (extracapsular neck), intertrochanteric, and subtrochanteric regions (FIG 1C).

PATHOGENESIS
- The hip may be fractured by means of a direct blow to the hip area or an indirect force applied to the limb.
- While simple falls are a frequent cause of hip fractures in the elderly, they are less common in children.
- An axial load to the femur as in a fall from height or a motor vehicle accident may result in hip fracture.
- A direct blow from the side may result in hip fracture.
- A violent twisting force to the limb may fracture the hip.

NATURAL HISTORY
- Untreated proximal femoral physeal separations that are completely displaced have a poor prognosis because of the high likelihood of avascular necrosis of the capital femoral epiphysis and poor apposition for healing.
- Minimally displaced proximal femoral physeal separations have a better prognosis, much like those of an acute slipped capital femoral epiphysis. Untreated they are likely to heal, but there is a possibility of avascular necrosis.
- Intra-articular fractures of the femoral neck that are undisplaced may heal but also may displace.
  - Displaced fractures have a poor prognosis for healing because they are intra-articular and therefore will not generate much subperiosteal new bone.
  - Furthermore, there usually is not good bony apposition.
- Extra-articular fractures of the femur (low neck, intertrochanteric, and subtrochanteric fractures) have a good prognosis for healing but tend to result in shortening, external rotation, and sometimes varus if untreated.

PATIENT HISTORY AND PHYSICAL FINDINGS
- A routine history is obtained to elicit the mechanism and energy of injury. Concomitant injury and comorbidities must be recognized.
The patient will be unable to bear weight.
Typically the affected limb appears shortened and externally rotated (FIG 2).

IMAGING AND OTHER DIAGNOSTIC STUDIES
Generally, plain films are adequate to diagnose and plan treatment for hip fractures (FIG 3).
Technetium bone scanning or MRI may indicate if the capital femoral epiphysis is perfused, but the accuracy is questionable early on and the avascularity may not be reversible even if diagnosed. Reductive treatment should not be delayed for these imaging studies.

DIFFERENTIAL DIAGNOSIS
- Pelvic fracture
- Slipped capital femoral epiphysis
- Synovitis
- Traumatic hemorrhrosis of hip

NONOPERATIVE MANAGEMENT
- Nondisplaced or minimally displaced proximal femoral physeal separations and truly undisplaced neck fractures can be immobilized in a spica cast, but followed closely (in a few days) to watch for displacement. Displacement requires reduction and fixation.
- Extra-articular fractures (low neck, intertrochanteric, and subtrochanteric fractures) in children less than 6 years old can be treated by closed manipulation and spica casting. Shortening more than 1.5 cm or varus of more than 15 degrees indicates a need for open reduction and internal fixation (ORIF).

SURGICAL MANAGEMENT
- All displaced proximal femoral physeal separations should be reduced and fixed.
- All displaced intra-articular femoral neck fractures should be reduced and fixed. It may be prudent to fixate undisplaced fractures to prevent displacement.
- Extra-articular hip fractures should be treated by ORIF in children age 6 or older, younger children whose fracture cannot be reduced closed, children with polytrauma, and those with wounds or skin conditions that would preclude casting.

Preoperative Planning
The injured hip should be evaluated under anesthesia using fluoroscopy.
Physeal separations and intra-articular neck fractures that can be reduced anatomically should be treated by percutaneous fixation: pins in infants and toddlers (FIG 4A,B), screws in older children (FIG 4C,D).

FIG 2 • The affected limb appears shortened and externally rotated.
FIG 3 • AP and lateral radiographs of the proximal femur.
FIG 4 • Fixation of an intra-articular femoral neck fracture. A. Displaced fracture. B. Pins are drilled from the lateral femoral cortex retrograde across the fracture. For toddlers, pins are sufficient. Fractures below the physis in older children need screws. (continued)
Extra-articular fractures that are stable after reduction should be immobilized in a spica cast.

Positioning
- Positioning should be supine on a radiolucent table. A fracture table is generally not necessary (FIG 5A).

Closed Reduction and Percutaneous Fixation
- This technique is suitable for proximal femoral physeal separations and intra-articular neck fractures.
- With fluoroscopy engaged, the hip is examined under anesthesia. If displaced, it should be reduced, usually by traction and internal rotation and abduction (TECH FIG 1A).
- If the fracture can be anatomically reduced, the surgeon should proceed with percutaneous fixation; if not, open reduction should be undertaken.
- Percutaneous fixation is inserted from laterally, just below the greater trochanteric apophysis and up the femoral neck as visualized under the C-arm (TECH FIG 1B).
Open reduction and internal fixation with pins or screws

- It is customary to use smooth pins for physeal separations or neck fractures in very young children. In older or larger children, cannulated screws are necessary. Screws should stop short of the physis unless there is so little room between the physis and fracture that adequate fixation is precluded.
- A lateral view, usually by frogging the hip, is necessary to confirm pin placement.
- Two pins are usually sufficient to provide safe fixation. A total of three is even better, but three are often difficult to insert.
- Once reduction and pin placement are confirmed by fluoroscopy, two planes, pins are cut and left protruding from the lateral femoral cortex for later removal, or drilling is performed over pins (TECH FIG 1C) and cannulated screws are placed (TECH FIG 1D).
- Because there may be a tense hemarthrosis that tamponades flow in the retinacular vessels of the neck, it may be wise to aspirate the joint capsule to evacuate or decompress the hip joint.

The anterior hip capsule is exposed (TECH FIG 2C).
- The hip capsule is incised longitudinally and “T”-ed if necessary to visualize within (TECH FIG 2D).
- The hematoma is evacuated.
- The fracture is reduced under direct vision (TECH FIG 2E).
- It is often necessary to pull the neck “up” with a bone hook to get it reduced. Reduction is confirmed by palpation and then fluoroscopy.
- Fixation is then performed from the lateral femur as described above.
OPEN REDUCTION AND INTERNAL FIXATION WITH FIXED-ANGLE PLATE AND SCREWS

Exposure and Fracture Reduction
- It is contemplated that the fracture will be fixed with a pediatric-sized lag-screw side-plate device.
- The hip is approached from laterally. An incision is made from just proximal to the greater trochanter, extending about 4 to 5 inches distally (TECH FIG 3A). The fascia lata is split in line with its fibers (TECH FIG 3B).
- The vastus fascia is cut with a “hockey stick” incision, starting anteriorly just distal to the apophysis of the greater trochanter (TECH FIG 3C). The incision is curved posteriorly and then extends distally in the posterior third of the vastus fascia. The muscle is elevated anteriorly, exposing the lateral femoral cortex.
- The fracture is reduced by direct manipulation.

Fracture Fixation
- A guidewire is then drilled up the center of the femoral neck (TECH FIG 4A). The angle the guidewire makes with the femoral shaft is dictated by the fixation device to be used. Generally a fixed-angle plate–lag screw combination will be used.
- The guidewire should be confirmed to be centered in the neck on anteroposterior (AP) and lateral C-arm views. The guidewire need not cross the capital femoral physe.
- The proper length of lag screw is measured (TECH FIG 4B).
- The channel for the lag screw is reamed (TECH FIG 4C) and tapped (TECH FIG 4D). The lag screw is inserted (TECH FIG 4E).
- A side plate is selected; usually three or four holes is sufficient. It is passed over the lag screw (TECH FIG 4F).
- The plate is secured to the femur with appropriate screws and fixed with a compression screw to the lag screw (TECH FIG 4G).
- Reduction and fixation are checked by fluoroscopy. Closure is routine.
Internal fixation of extra-articular hip fracture. A. After fracture reduction, a guidewire is inserted from the lateral femoral cortex up the femoral neck. The angle the wire makes with the lateral cortex should match the angle of the fixation device (usually 135 degrees). B. The length of the intended lag screw is measured from the protruding guidewire. The lag screw should stop short of the physis. C. Reaming is accomplished over the guidewire to accommodate the lag screw and the barrel of the side plate. D. The channel is tapped because the child’s bone is usually quite hard. E. The lag screw is inserted. F. The side plate is placed. G. The plate is secured to the femur with cortical screws and the compression screw locks the lag screw in the side plate.

**POSTOPERATIVE CARE**

- Hip fractures fixed with pins, fractures in small children, and fractures in patients who cannot refrain from weight bearing should be immobilized for 4 to 6 weeks in a spica cast.
- Controlled children can be maintained non-weight bearing with crutches.
- Pins should be removed after fracture healing. Screws and hardware should be removed before they are covered by new bone growth.

**OUTCOMES**

- Satisfactory healing is to be expected in most cases.
- Stiffness after cast removal usually resolves without treatment.
- Avascular necrosis may have a benign course similar to that of Perthes disease or may result in relentless disintegration of the femoral head, for which there is no satisfactory treatment in a child.

**COMPLICATIONS**

- Avascular necrosis
- Varus malunion
- Nonunion
- Leg-length discrepancy

**REFERENCES**

DEFINITION
- Femoral shaft fractures in children occur with an incidence of 20 per 100,000. They constitute 2% of all pediatric fractures.1,7
- In the very young child who presents with a femoral shaft fracture, child abuse must be considered, especially if the child is not yet walking.
- In the child who has a history of multiple fractures, osteogenesis imperfecta might be the underlying cause and is often mistaken for child abuse in the young child.
- In children who sustain multiple traumatic injuries, the nature and severity of each injury must be considered to optimize treatment.

ANATOMY
- The limb bud develops at about 4 weeks of gestation, the femoral shaft serving as the primary ossification center. The proximal ossification center is seen by 6 months and the distal femoral ossification center appears at 7 months.
- The femur is initially composed of weaker woven bone, which is gradually replaced with lamellar bone during childhood.
- Both the endosteal circulation and the periosteal circulation supply the femur. The profunda femoris artery gives rise to four perforating arteries, which enter the femur posteromedially. The majority of the blood is supplied by the endosteal circulation. During fracture healing, however, the majority of the blood is supplied by the periosteal circulation.
- The femoral shaft flares distally, forming the supracondylar area of the femur.

PATHOGENESIS
- Age is an important factor to consider in terms of the pathogenesis of the injury. The degree of trauma required to cause injury increases exponentially as the character of the bone changes and gradually becomes stronger and larger from infancy to adolescence. Low-energy injuries resulting in fractures may point to a pathologic nature of the condition, except in toddlers, in whom low-energy femur fractures are common.
- The radiographic appearance of the fracture usually reflects the mechanism of injury and the force applied. High-velocity injuries usually present with more complex, comminuted patterns.
- The position of the fracture fragments after the injury depends on the level of the fracture and reflects the soft tissue and muscle forces acting on the femur.

PATIENT HISTORY AND PHYSICAL FINDINGS
- In most cases, there is a history of a traumatic event.
- The clinician inspects the lower extremity and looks for open wounds, bruising, or obvious deformity.
- In the setting of an isolated femur fracture, the thigh appears swollen with minor bruises and abrasions. Shortening may also be present.
- Open wounds may change the management of this injury; obvious deformity helps in the initial diagnosis.
- The clinician palpates the length of the lower extremity, feeling for bony deformity and checking compartments carefully for tension. Tense compartments may indicate current or developing compartment syndrome.
- The affected extremity should be checked to ensure that there is no vascular or neurologic injury.
- The clinicians should check carefully for femoral, popliteal, dorsalis pedis, and posterior tibial pulses. Diminished pulses may indicate vascular compromise or compartment syndrome. If diminished, they should be rechecked with Doppler.
- Sensation to light touch is tested along the length of the entire lower extremity. Decreased sensation in the lower extremity may indicate nerve damage.
- Motor examination may be difficult because of injury. Ankle dorsiflexion and plantarflexion are tested. Diminished strength may indicate nerve damage or compartment syndrome or may also be secondary to pain.
- Examining reflexes may also be difficult. The clinician strikes the patellar and Achilles tendons with a reflex hammer and looks for contraction of the quadriceps and gastrocnemius, respectively. Diminished knee or ankle reflexes may indicate femoral or sciatic nerve injury or may also be secondary to guarding.
- In cases of high-energy trauma, concomitant injuries to the skin and soft tissue as well as other organ systems are usually present.
- The knee is examined to ensure that no ligamentous injury is present. This examination may be performed under anesthesia.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- Standard high-quality anteroposterior (AP) and lateral radiographs of the femur are usually all that is needed to define the extent and severity of the injury (FIG 1).
- Radiographs should include the joints above and below the fracture site to avoid missing any concomitant injuries.
- Rarely, a CT scan may be helpful in assessing more complex injury patterns. It also helps in revealing subtle injuries that may not be apparent on radiographs, such as stress fractures, and aids in characterizing intra-articular injuries.

DIFFERENTIAL DIAGNOSIS
- Soft tissue trauma
- Stress fracture
- Tumor
- Metabolic conditions
NONOPERATIVE MANAGEMENT

- Management of femoral shaft fractures depends on the age of the patient.
- In infants, stable femoral shaft fractures can be treated in a Pavlik harness or a splint.
- In children younger than 6 years, closed reduction and casting is used in the vast majority of cases.

Surgical Management

- In children younger than 6 years, closed reduction and casting is successful for most femoral shaft fractures.
- For older children and adolescents, 3 weeks of skeletal traction followed by spica casting was once common but has been replaced by internal or external fixation in most cases.

Preoperative Planning

- A detailed review of the clinical findings and all appropriate imaging studies is performed before the procedure.
- Shortening should be determined to be less than 2 cm using a lateral radiograph, although some suggest spica casting can be accomplished regardless of shortening.\(^6\)
- If the mechanism of injury is considered low energy, a single-leg “walking spica” can be considered, as it has been shown to be as effective as traditional spica casting and may also decrease the burden of care on the family.\(^4\)
- The presence of concomitant injuries should be considered as well as factors that may hinder or complicate treatment.

Positioning

- The child is taken to the operating room or sedation unit and placed in the supine position on the table.
- The injured extremity is casted first, and then the patient is transferred to a spica table.

TRADITIONAL SPICA CASTING

- A long-leg cast is placed with the knee and ankle flexed at 90 degrees (TECH FIG 1A). Because of recent reports of compartment syndrome of the leg after spica casting for pediatric femur fractures,\(^6,9\) many centers (ours included) have been using less hip and knee flexion and not including the foot for the cast of the injured leg.
- Extra padding in the popliteal fossa is applied. To avoid vascular compromise, care must be taken not to flex the knee once the padding is in place.
- A valgus mold at the fracture site is used to prevent varus deformity (TECH FIG 1B).
- The patient is transferred to a spica table, where the weight of the legs is supported with manual traction.
- The hip is placed at 90 degrees of flexion and 30 degrees of abduction. Fifteen degrees of external rotation at the hip is used to allow alignment of the proximal and distal fragments (TECH FIG 1C,D).
- The remainder of the spica cast is placed while holding the fracture out to length.
- Care should be taken to avoid excessive traction, which increases the risk of compartment syndrome and skin sloughing.
- New AP and lateral radiographs are taken to ensure acceptable anatomic alignment.
- Gore-Tex liners are used at some institutions to prevent diaper rash and superficial infections.
WALKING SPICA CASTING

- A walking spica is becoming a popular choice for low-energy femur fractures.
- The cylinder cast should be applied with about 50 degrees of knee flexion.
- The foot remains uncovered with the cast stopping in the supramalleolar area, which is protected with extra padding.
- Before the remainder of the cast is applied, the hip is flexed to 45 degrees and remains abducted to 30 degrees with 15 degrees of external rotation (TECH FIG 2A,B).
- The pelvic band is applied with multiple layers of stockinette folded on the abdomen to prevent abdominal compression from the casting. These folded layers of stockinette are removed after the pelvic band is placed (TECH FIG 2C).

PEARLS AND PITFALLS

<table>
<thead>
<tr>
<th>Indications</th>
<th>Spica casting is best used for children 1 to 6 years old with isolated femoral shaft fractures.</th>
</tr>
</thead>
</table>
| Contraindications | Shortening of more than 2 cm (controversial)  
Massive swelling of the thigh  
Associated injury that precludes cast treatment |
| Walking spica | Effective for low-energy isolated femur fractures  
Toddlers typically pull-to-stand and begin walking in 2 to 3 weeks. |
POSTOPERATIVE CARE

- A significant burden of care is placed on the family of a child with a spica cast, including cast care, travel difficulties, and loss of time at work.
- We counsel the family, immediately after reduction in casting, that wedging of the cast may be necessary at about 10 to 14 days after injury.
- We schedule the family to return 1 week and 2 weeks after injury; at that time true AP and lateral radiographs are obtained of the injured femur in the cast. If there is unsatisfactory alignment or either angulation or shortening, we will wedge the cast at the clinic and repeat radiographs. This frequently avoids unnecessary trips back to the operating room in the postoperative period for loss of reduction.
- Prior to callus formation, if shortening of more than 2 cm occurs, one of three options may be required: cast change, traction, or external fixation.
- Shortening of more than 2 cm once callus has formed may be treated with osteoclasis and lengthening techniques at a pace of 1 mm per day.
- At union, acceptable angulation and shortening varies by age (Table 1).

OUTCOMES

- Typically the spica cast is worn for 4 to 8 weeks, depending on the extent of the injury.
  - Infant fractures heal in 3 to 4 weeks.
  - Toddler fractures heal in 6 weeks.
- On removal of the cast, children are encouraged to stand up and walk as soon as they are comfortable.

DEFINITION
- Femoral shaft fractures occur in children with a bimodal age distribution peaking at ages 2 and 12.
- The peak in age distribution at age 2 is due to relative weakness of primarily woven bone at a time when ambulation increases the risk of fall-related trauma.

ANATOMY
- Muscular deforming forces, if severe, increase the need for surgical fixation. In proximal and midshaft femoral shaft fractures, the proximal fragment tends to be forced into abduction and external rotation. This is more significant in proximal fractures than in midshaft fractures.
- Fractures of the distal third of the femoral shaft tend not to deform greatly, while supracondylar femoral fractures are often forced into apex posterior angulation.

PATHOGENESIS
- In toddlers, these injuries tend to be low energy and occur during normal activity. In adolescents, they tend to be higher-energy injuries that may result from motor vehicle, biking, or high-speed sporting accidents.
- Abuse should be considered in the infant or toddler with a femur fracture, especially if the child is nonambulatory.

PATIENT HISTORY AND PHYSICAL FINDINGS
- In an unconscious patient or a patient with an insensate lower extremity, deformity, erythema, crepitance, and swelling might indicate the presence of a femoral fracture.
- If child abuse is suspected, a skeletal survey should be obtained and Child Protective Services should be notified. Infants are more likely than toddlers to be the victims of child abuse in the setting of a femoral fracture.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- Anteroposterior (AP) and lateral radiographs of pelvis and femur are obtained. The hip and knee should be visualized on the femur radiograph or separately to evaluate possible associated injuries (FIG 1).
- Radiographs should be evaluated for fracture pattern, location, displacement, angulation, and shortening.

DIFFERENTIAL DIAGNOSIS
- In a child with an insensate extremity, the swelling and erythema caused by a femur fracture may resemble an infection.

NONOPERATIVE MANAGEMENT
- Nonoperative management (casting) is appropriate for an isolated femur fracture in a child younger than 6 years. Most children older than 6 years are now treated with some form of operative fracture stabilization.
- Nonoperative options include Pavlik harness or splints for children younger than 6 months and a spica cast for those older than 6 months.

SURGICAL MANAGEMENT
- Operative management of femoral shaft fractures should be considered in any femur fracture in a child older than 6 years. In younger children, polytrauma, head injury, high-energy trauma, an open fracture, severe comminution, or body habitus incompatible with spica cast care are relative indications for operative management.
- Surgical options include flexible nailing, plating, rigid intramedullary nailing, and external fixation.
- Indications for external fixation include polytrauma, concomitant head injury, open fracture with severe soft tissue damage or contamination, severe comminution, and very proximal subtrochanteric or distal diaphyseal-metaphyseal junction fracture.
- Midshaft transverse fractures are at a higher risk of refracture when treated with external fixation compared to other methods of stabilization.

FIG 1 • Preoperative radiograph of a 12-year-old boy who sustained a distal femoral shaft fracture.
Preoperative Planning
- The surgeon should determine where pins will be placed before surgery.
- In each fragment there must be at least 2 cm of intervening bone between the physis and the outermost pin and at least 2 cm between the fracture and the innermost pin.
- The appropriate pin size varies according to the device. The AO/Synthes device guide recommends 4.0-mm Schanz screws be used, while the EBI device guide recommends screws not larger than one third of the bone diameter.

Positioning
- The patient should be placed on either a radiolucent operating table or a fracture table. The latter is useful if preoperative reduction is desired.

**EBI DFS XS FIXATOR TECHNIQUE**

**Pin and Screw Placement**
- The first pin inserted should be one into the shorter or more difficult bone fragment.
- After making a stab incision over the first pin site, the surgeon dissects bluntly to the near cortex.
- The trocar is inserted into the soft tissue guide and seated onto the femur perpendicular to its long axis. The trocar is removed and the soft tissue guide is impacted gently to prevent slippage.
- The appropriate drill guide (based on the chosen screw size) is inserted into the soft tissue guide.
- After attaching a drill stop onto the appropriate bit, the surgeon drills through the near cortex, using the drill guide to keep the pilot hole perpendicular to the long axis of the bone. Drilling should stop once the near cortex is penetrated.
- The surgeon slides the bit up to the far cortex without drilling. The drill stop is adjusted so that the drill can be advanced no more than 5 mm (**TECH FIG 1A**). The surgeon then drills through the far cortex.
- Any tented skin is released.
- The surgeon slides the telescoping arm of the assembled fixator onto the screw in the appropriate position. The clamp bolt is not tightened.
- The soft tissue guide is inserted into another clamp position on the same telescoping arm. Again, the clamp bolt should be loose enough to allow translation of the soft tissue cover through the arm.
- Once the soft tissue guide has been seated on the near cortex, the clamp bolt is tightened to prevent loss of alignment. Repeating the above steps, a second screw is inserted in the position now occupied by the soft tissue guide (**TECH FIG 1B**).
- Once both screws have been placed in the first fragment, the above steps are repeated on the second fragment (**TECH FIG 1C**).
- The telescoping arm clamp bolts are tightened before final reduction.

**Final Reduction**
- The final reduction is made with a variety of adjustments.
- Length can be adjusted on each telescoping arm by either loosening the telescoping set screw and adjusting length manually or by loosening the compression-distraction screw and using this feature to adjust length (**TECH FIG 2A**).
- Any tented skin is released.
- The locking connector bolts can be loosened for the correction of angular deformity (**TECH FIG 2B**).
Each telescoping arm can also be rotated using the rotational set screw on the central body of the fixator (TECH FIG 2C). These can be loosened simultaneously to rotate the central body of the fixator to bring the central locking joints into the plane of correction (TECH FIG 2D).

Each telescoping arm is able to extend up to 2 cm. If more length is needed, a 4-cm arm may be used. This is especially useful when one arm is occupied by the T-clamp, which has no telescoping feature.

Alternative T-Clamp Technique
- If desired, the T-clamp can be used when the fracture pattern precludes placement of screws longitudinally in one of the bone fragments.
- The T-clamp is applied before the telescoping arm using the screw insertion technique described.
- After the T-clamp is in place, the screws for the telescoping arm are placed in the other fragment as in the standard configuration described above.

AO/SYNTHES TECHNIQUE USING PEDIATRIC FEMORAL SHAFT FRAME WITH COMBINATION CLAMPS

**Construct Application**
- Note: All Schanz screws must be coplanar if double stacking (for increased rigidity) or dynamization is desired.
- The most proximal screw and the most distal screw are inserted before inserting the inner pins. Screws should be placed with at least 2 cm of bone between the screw and the physis.
- The screw is inserted in the following manner.
  - A stab incision is made.
  - The trocar with protective sleeve is seated onto the femur by passing it through the incision.
  - The trocar is removed, the screw is inserted into the protective sleeve, and the surgeon drills until the screw is embedded in the far cortex.
  - If preferred, a power drill is used until the near cortex is penetrated; then the surgeon can drill into the far cortex by hand.
  - After inserting the outermost (most distal and most proximal) Schanz screws, the surgeon attaches a medium combination clamp to each screw.
- The carbon rod is attached to each clamp. The construct should now consist of four screws, two clamps, and one carbon rod.
- The fracture is reduced and the clamp bolts are tightened.
- Two additional clamps are attached to the carbon rod. These will attach the inner screws to the carbon rod.
- The two inner screws are inserted in the same fashion as the outer screws. There should be at least 2 cm of bone between the screw and the fracture. These screws are attached to the inner combination clamps and the bolts are tightened.
- The construct now consists of four screws, four clamps, and one carbon rod (TECH FIG 3A).
- A second carbon rod may be added if additional stiffness is desired and all screws are coplanar. The rod is secured to each screw with a combination clamp.
- If this step is completed, the construct will consist of four screws, eight clamps, and two rods (TECH FIG 3B).
Dynamization

- Dynamization can be accomplished only in a double-stacked construct. To dynamize the fixator, the outer bolts on the proximal pins and the inner bolts on the distal pins will be adjusted as follows. The bolt is loosened, a dynamization clip is inserted between the rod vise plates, and the bolt is retightened. This procedure is repeated for all four appropriate bolts (TECH FIG 4A).
- The dynamization clips can be used in the postoperative setting to increase axial loading across the fracture site or intraoperatively for compression or distraction of the fracture.
- Intraoperative distraction or compression is achieved by dynamizing the fixator, attaching the distractor device adjacent to a dynamized clamp (TECH FIG 4B), turning the distractor adjustment ring to either distract or compress, removing the dynamization clips after dynamization or compression, and retightening the clamps.

Assembly of this fixator requires screw insertion of one bone fragment to be completed before inserting screws in the other fragment. Therefore, Schanz screws will not be inserted in the outside-to-inside fashion used for the combination clamps.

- The first Schanz screw should be an outer screw, inserted with at least 2 cm of bone between the screw and the physis. A multipin clamp is attached to this first screw and the screw is drilled into the femur. The clamp may be held parallel to the femoral shaft to ensure that the screw enters the femur perpendicularly.
- The second Schanz screw is inserted through the opposite end of the clamp, with at least 2 cm of bone between the screw and the fracture site. This screw and all subsequent screws should be inserted as described above, with a stab incision, protective sleeve seating, and screw guidance with the sleeve (TECH FIG 5A).
Up to two additional Schanz screws may be inserted through the multipin clamp if necessary. This completes assembly of the hemifixator.

These steps are repeated for the other bone fragment.

The multipin clamp vise plate bolts are tightened on each hemifixator.

The carbon rod is attached to each multipin clamp.

The fracture is reduced and the rod clamping bolt and rod attachment bolt are tightened (TECH FIG 5B).

A second rod may be added to the construct to increase the stiffness of the fixator. This is accomplished with two rod attachment devices (TECH FIG 5C).

Modular frame constructs may be created if the fracture pattern precludes coplanar insertion of Schanz screws. This is accomplished by sequential assembly of modules that are then connected by a spanning carbon rod.

The first screw, which should be an outer screw, is inserted with at least 2 cm of bone between the screw and the physis.

The second screw, an inner screw, is inserted into the same fragment. There should be at least 2 cm of intervening bone between the screw and the fracture. This screw need not be coplanar with the first screw. This screw and subsequent screws should be inserted as described above, with a stab incision, protective sleeve seating, and screw guidance with the sleeve.

Combination clamps are attached to each screw and the bolts are tightened.

A carbon rod is connected to each combination clamp. This completes the assembly of the first module.

The second module is built in the same fashion as the first: the outer screw is inserted, then the inner screw; combination clamps are attached to the screws; and then the clamps are connected with a carbon rod. Each module should consist of two Schanz screws, two combination clamps, and a carbon rod.

Once each module has been constructed, a combination clamp is attached to each carbon rod. The placement of these clamps should be as follows:

The first clamp is placed on the proximal module distal to the most distal screw and the second clamp is placed proximal to the most proximal screw.

These combination clamps are connected to a third carbon rod.

If the spanning clamps are placed correctly, the fixator will have a Z conformation (TECH FIG 6A). If not, the fixator will have an I formation.

The fracture is reduced before tightening the spanning rod clamps.

The spanning rod combination clamps are tightened once adequate reduction is obtained.

To increase the stiffness of the fixator and add rotational stability, a second spanning rod is added. The placement of the second set of spanning clamps should be as follows:

The first clamp is placed on the proximal module proximal to the most proximal screw and the second clamp is placed on the distal rod distal to the most distal screw.

These combination clamps are connected to a fourth carbon rod.

If this second set of spanning clamps have been placed correctly, the modular rods and the spanning rods will have an hourglass configuration (TECH FIG 6B).
PEARLS AND PITFALLS

**Evaluation**
- Although many pediatric femur fractures are isolated injuries, high-energy fractures are often associated with head, chest, or abdominal trauma.
- The injured extremity must be thoroughly evaluated for associated trauma.
- Femoral shortening across the fracture site is best visualized with a lateral femur radiograph before traction is applied.
- Corner fractures and bucket-handle fractures are more specific than spiral fractures for nonaccidental injury.

**Fixation**
- Remodeling potential declines significantly after age 10.
- Angulation across the fracture site is better tolerated proximally than distally and better in the sagittal plane than in the coronal plane.

**Medicolegal**
- Closed treatment of femoral fractures is a common source of malpractice litigation in the field of pediatric orthopaedics.

---

**TECH FIG 6** • A. Basic modular frame with connected modules. B. Fourth bar is added to frame configuration to increase stiffness and rotational stability. The fourth bar should span the length of the frame, connecting the first and second modules. (Copyright Synthes, Inc., or its affiliates. All rights reserved.)

**FIG 2** • Postoperative radiographs from the patient in Figure 1 on postoperative day 1 (A), before external fixator removal on postoperative day 63 (B), and at last follow-up on postoperative day 217 (C).
POSTOPERATIVE CARE
- Pin care is essential in avoiding pin-track infection. This skill must be taught in the postoperative setting and reviewed at each office visit.
- Antibiotics with adequate coverage of skin flora should be prescribed at the first sign of pin-track infection.
- Some advocate removal of the external fixator as soon as bridging callus is seen, with subsequent casting if necessary. Others believe the fixator should be left in place until three of four cortices are bridged by callus.
- A typical radiographic evolution of this injury when treated with external fixation is shown in FIGURE 2.

OUTCOMES
- In one series of 37 femur fractures treated with external fixation, the average duration of fixation was 3 to 4 months (range 2 to 5 months). In all but one case, union was achieved at the time of fixator removal.4
- Risk of refracture may be as high as 20% after fixator removal.2,4
- Pin-track infections occur in about 65% of cases. These can almost always be managed successfully with oral antibiotics; fixator removal is rarely required.
- While clinically insignificant malunion is often seen, malunion requiring surgical correction is rare.

COMPLICATIONS
- Pin-track infection
- Deep infection
- Knee stiffness
- Unsightly thigh scars
- Delayed union
- Refracture
- Malunion
- Leg-length discrepancy

REFERENCES
DEFINITION

- Femoral shaft fractures in children occur with an incidence of 20 per 100,000. They constitute 2% of all pediatric fractures.
- In the very young child who presents with a femoral shaft fracture, child abuse must be considered, especially if the child is not yet walking. In the child who has a history of multiple fractures, osteogenesis imperfecta might be the underlying cause and is often mistaken for child abuse in the young child.
- In children who sustain multiple traumatic injuries, the nature and severity of each injury must be considered to optimize treatment.

ANATOMY

- The limb bud develops at about 4 weeks of gestation, with the femoral shaft serving as the primary ossification center. The proximal ossification center is seen by 6 months and the distal femoral ossification center appears at 7 months.
- The femur is initially composed of weaker woven bone, which is gradually replaced with lamellar bone during childhood.
- Both the endosteal circulation and the periosteal circulation supply the femur. The profunda femoris artery gives rise to four perforating arteries, which enter the femur posteromedially. The majority of the blood is supplied by the endosteal circulation. During fracture healing, however, the majority of the blood is supplied by the periosteal circulation.
- The femoral shaft flares distally, forming the supracondylar area of the femur. This area serves as the entry point for retrograde nailing with flexible intramedullary nails.

PATHOGENESIS

- Age is an important factor to consider in terms of the pathogenesis of the injury. The degree of trauma required to cause injury increases exponentially as the character of the bone changes and gradually becomes stronger and larger from infancy to adolescence. Low-energy injuries resulting in fractures may point to a pathologic nature of the condition.
- The radiographic appearance of the fracture usually reflects the mechanism of injury and the force applied. High-velocity injuries usually present with more complex, comminuted patterns.
- The position of the fracture fragments after the injury depends on the level of the fracture and reflects the soft tissue and muscle forces acting on the femur.

PATIENT HISTORY AND PHYSICAL FINDINGS

- In most cases, there is a history of a traumatic event.
- In an isolated femur fracture, the thigh appears swollen, with minor bruises and abrasions. Shortening may also be present.
- The affected extremity should be checked to ensure that no vascular or neurologic injury is present.
- In cases of high-energy trauma, concomitant injuries to the skin and soft tissue as well as other organ systems are usually present.
- An examination of the knee is likewise performed to ensure that no ligamentous injury is present. This may be performed under anesthesia.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Standard high-quality anteroposterior (AP) and lateral radiographs of the femur are usually all that is needed to define the extent and severity of the injury (FIG 1).
- Radiographs should include the joints above and below the fracture site to avoid missing any concomitant injuries.
- Rarely, a CT scan may be helpful in assessing more complex injury patterns. It also helps in revealing subtle injuries that may not be apparent on radiographs, such as stress fractures, and aids in characterizing intra-articular injuries.

DIFFERENTIAL DIAGNOSIS

- Soft tissue trauma
- Stress fracture
- Tumor
- Metabolic conditions

FIG 1 • Preoperative radiographs of a 7-year-old boy who sustained a spiral diaphyseal femoral shaft fracture while playing football. This injury was treated with titanium elastic nails.
NONOPERATIVE MANAGEMENT
- Management of femoral shaft fractures depends on the age of the patient.
- In infants, femoral shaft fractures can be treated with a Pavlik harness or a splint.
- In children less than 6 years of age, nonoperative management is the treatment of choice. Nonoperative management usually consists of:
  - Closed reduction under sedation or anesthesia as needed
  - Placement of a hip spica cast to maintain reduction for 6 to 8 weeks
  - Correcting rotational and angular alignment is of the utmost importance in treatment. Shortening of up to 2 cm is acceptable.

SURGICAL MANAGEMENT
- In older children and adolescents, nonoperative management is not well tolerated.
- General recommendations for titanium elastic nails are:
  - Children at least 5 years old (ideal for children 6 to 12 years of age)
  - Fractures of the middle 70% of the diaphysis
  - Length-stable fracture patterns. Some difficulty may be encountered in more complex and comminuted fracture patterns.

Preoperative Planning
- A detailed review of the clinical findings and all appropriate imaging studies is done before the procedure.
- The diameter of the nail is predetermined by measuring the isthmus of the femoral shaft. The nail to be used is usually 40% of the narrowest diameter. For instance, if the isthmus measures 1 cm, a 4-mm nail is used.
- The presence of concomitant injuries should be considered, as well as factors that may hinder or complicate treatment.

Positioning
- The patient is positioned in the supine position. We prefer using a fracture table (FIG 2).
- The groin area is adequately padded before application of the post.
- The affected extremity is abducted 15 to 30 degrees to allow room for nail placement. The uninjured leg can be held by the ankle (the well-foot holder) and “scissored” with extension of the hip so that it does not block the lateral radiographic view.
- We generally avoid the well-leg holder that places the well leg with the hip and knee flexed high above the rest of the patient. Compartment syndrome has been associated with this positioning for femoral shaft fracture treatment.
- A distraction force is applied to the affected extremity through the foot using a foot holder. If there is significant soft tissue injury to the leg, the distraction force may be applied through a guide pin. However, a guide pin is rarely necessary in children.
- The extremity is then prepared and draped.

FIG 2 • The patient is properly positioned in the fracture table, the landmarks are identified fluoroscopically, and the proper incision sites are marked.

RETROGRADE FLEXIBLE INTRAMEDULLARY NAILING

Nail Introduction and Fracture Reduction
- Once the patient is properly positioned in the fracture table, the best possible reduction of the fracture is obtained.
- The patient is draped in the standard manner.
- The nail entry site is identified using an image intensifier.
- The distal femoral physis is identified and this position is marked on the skin to avoid dissection in this area.
- A 2-cm incision is marked out both medially and laterally at the level of the distal femoral physis.
- The incision is made and carried through the fascia and quadriceps muscle, observing meticulous hemostasis.
- A drill is placed (with a soft tissue protector) through the incision site against the distal femoral metaphysis. The starting point is the midpoint of the femoral shaft in the AP plane (TECH FIG 1A).
- The size of the drill bit used is largely dependent on the size of the nail; the drill bit should be slightly larger than the nail (eg, a 4.5-mm drill bit is used when using a 4.0-mm nail).

- The drill is inserted, and once the femoral cortex has been breached, the drill is angled obliquely (TECH FIG 1B).
- The nails are prebent into a gentle C shape before insertion (TECH FIG 1C).
- The first nail is inserted into the entry site and gently tapped into the femur. The position of the nail is checked under fluoroscopy in both the AP and lateral views to ensure proper nail placement (TECH FIG 1D).
- Once the tip of the nail has reached the fracture site, the fracture is reduced before further advancement of the nail. Reduction of the fragments is documented in both the AP and sagittal planes.
- When reduction is obtained, the nail that is more difficult to pass is introduced through the fracture site.
- Once the first nail has crossed the fracture line, the same steps for insertion are followed for introduction of the second nail (TECH FIG 1E).
- Alternatively, the second nail may be inserted immediately after the first nail to the level of the fracture site. Once proper reduction of the fracture is obtained, the nails are then advanced past the fracture site alternately as described in the technique above.
Once the incision has been made, the entry point for the nail is identified 2 cm superior to the growth plate at the midpoint of the femur anteroposteriorly. A 4.5-mm drill bit is used to make the starting point. B. Once the cortex has been entered the drill is angled obliquely to fashion a tract. C. The nail is bent in a gentle C shape before insertion. D. The first nail is inserted until it reaches the fracture line. E. Once the first nail has reached the fracture line, the second nail is inserted in the same fashion.

Final Nail Placement

- When reduction has been confirmed and both nails have sufficiently crossed the fracture line (TECH FIG 2A–C), both nails are advanced a few millimeters and their position is checked with the image intensifier in both the AP and lateral planes (TECH FIG 2D).
- Once the position of both nails has been confirmed, they are gradually advanced to their final proximal point (TECH FIG 2E).
- The lateral nail (nail entering through the lateral cortex of the femur) should end at the apophysis of the greater trochanter. The medial nail should come to rest at the medial end side of the calcar at the level of the hip (TECH FIG 2F,G).
- After the final position of the nails has been confirmed, the nails are backed out a few centimeters, cut to the proper length, and gently tapped back into their final position with the ends of the nail resting flush against the femur. Bending the end of the nails will cause undue irritation of the skin and soft tissue.
- The final fracture configuration is checked (TECH FIG 2H,I). If there is a significant gap between the fracture fragments, the distraction is released and the surgeon gently impacts the fracture fragments together.
- A layered closure is performed.
- Rotational alignment of the extremity is evaluated and any malrotation is corrected before leaving the operating room.
Chapter 13  FLEXIBLE INTRAMEDULLARY NAILING OF FEMORAL SHAFT FRACTURES  

TECH FIG 2 • (continued) E. The lateral nail should end at the apophysis of the greater trochanter, the medial nail at the calcar of the femoral neck. F. The distal ends of the nail should be flush with the femoral metaphysis. G. The final configuration of the nails should provide adequate three-point fixation. H, I. AP and lateral radiographs of the femur of the patient in Figure 1, showing adequate nail placement.

PEARLS AND PITFALLS

Indications
- The flexible nailing technique is most successful for children ages 5 to 12, weighing less than 50 kg, with length-stable fractures. Very proximal, distal, or length-unstable fractures can be treated with flexible nailing, but the complication rate is higher and immobilization in a cast may be necessary as an adjunct to treatment.

Preoperative planning
- Proper selection and preparation of the nails are crucial, as well as proper patient selection. The nail sizes and the entry points should be symmetric.

Fracture fixation
- Proper nail configuration must be achieved to obtain three-point fixation. The nails should be gently curved before insertion to ensure maximum cortical contact. If insertion or nail passage may be difficult or the entry site is complicated by soft tissue injury, an anterograde method of insertion through the greater trochanter may be used for one or both nails.

Difficulty in reduction
- An instrument referred to as the “F tool” is a great aid to reduction.

Skin irritation
- To avoid skin irritation, the nails should be cut so that they lie flush with the metaphysis of the distal femur, with only about 1 to 2 cm of the nail outside the cortical entry site.

POSTOPERATIVE CARE
- We prefer a knee immobilizer in the immediate postoperative period to reduce the incidence of soft tissue irritation of the knee and to increase the child’s comfort.
- Weight bearing is instituted immediately after surgery as tolerated.
- Postoperative analgesics are maintained for continued pain relief and to maximize the rehabilitation period.

OUTCOMES
- Multiple studies have reported good to excellent outcomes in femoral shaft fractures treated with flexible intramedullary nails.3-4,7
- Flynn and coworkers5 in a multicenter trial, reported excellent results in 67% (39) of cases and satisfactory results in 31% (18); there was one poor result due to malrotation.
- Mehlman and associates10 showed in a biomechanical study that if an acceptable starting point is achieved, retrograde nailing is more stable for fractures of the distal third of the femoral diaphysis.
- Flynn and associates6 reviewed their first 50 cases and found that insertion site irritation was the most common problem encountered (18% of cases). Very proximal fractures were more challenging to treat and older, larger children were best managed with additional periods of adjunctive immobilization.
- Moroz and colleagues,11 in a review of 234 femur fractures in 229 children, found excellent results in 150 (65%), satisfactory in 57 (25%), and poor in 23 (10%). The poor outcomes were secondary to length discrepancy in 5 cases, unacceptable angulation in 17, and failure of fixation in 1. They likewise reported a correlation with poor outcome in older children (older than 11 years) and in children who weighed more than 49 kg.
COMPLICATIONS

- Nonunion
- Delayed union
- Malunion (angular and rotational deformity)
- Leg-length discrepancy (shortening and overgrowth)
- Compartment syndrome
- Neurovascular injury
- Implant-related complications

REFERENCES

SURGICAL MANAGEMENT

- Plate osteosynthesis of pediatric femur fractures allows stable fixation with good results.\(^2,3,5,7,12\)
  - This traditionally requires a large exposure with soft tissue disruption.
  - Submuscular bridge plating results in stable fixation while minimizing soft tissue dissection.
  - In unstable fractures, it reliably maintains length and alignment that may be difficult to maintain with either immediate spica casting or elastic intramedullary nails.
  - Minimally invasive plating techniques avoid a large dissection and leave the soft tissues intact, allowing rapid “biologic healing.” This has led to more appeal for plating.
  - The technique of femoral shaft plating has evolved with a better understanding of plate mechanics.\(^9\)
  - The indications for this technique are unstable comminuted or oblique femur fractures in ages 6 to skeletal maturity.

PROVISIONAL REDUCTION

- Patients are positioned on a fracture table, and a provisional reduction is obtained with boot traction.
- The well leg is extended if the fracture table allows. Thus, the legs are scissored in an anteroposterior (AP) direction (TECH FIG 1).
  - The well leg can also be positioned on a well-leg holder.
  - This allows the fluoroscopy to be aimed perpendicular to the fractured leg to get a good lateral image for percutaneous screw placement.
- A radiolucent table can also be used if there is enough assistance for traction.
- The goal of the provisional reduction is to restore length and rotation.

IMPLANT SELECTION AND PREPARATION

- The final reduction, particularly in the AP plane, can be done with the plate and screws.
- A 4.5-mm narrow low-contact dynamic compression plate (LC-DCP) is chosen for most patients.
  - Locking plates may be used in osteopenic patients or in proximal or distal fractures in which the amount of available room for screws is compromised.
  - Given the percutaneous nature of screw placement, self-tapping screws are used to facilitate insertion.
  - The usual plate length is from 10 to 16 holes, depending on the fracture location and patient size.
  - Plate length is determined by placing the plate over the anterior thigh and using imaging to confirm the appropriate length.
- As a general rule, the plate spans from the trochanteric apophysis to the distal femoral metaphysis.
- If possible, length should allow six screw holes proximal and distal to the fracture.
- Some fracture locations may allow for only two or three holes.
- A table plate bender is used to contour the plate.
  - This usually involves a small bend to accommodate both the proximal femur and the distal metaphysis.
  - It is important to contour the plate as close to anatomic as possible, as the femur will reduce to the contour of the plate with screw placement.
After the plate is contoured, it is again placed on the anterior thigh, and imaging is used to “shadow” the lateral aspect of the femur to confirm the contour (TECH FIG 2).

- It is not necessary to contour the plate to fit the normal anterior bow of the femur.
- In our experience, there has been no misalignment secondary to a poorly contoured plate.

**INTERNAL FIXATION**

**Plate Placement**

- A small incision (about 4 to 7 cm) is made over the distal lateral femur and through the tensor fascia to expose the obliquely oriented distal fibers of the vastus lateralis.
- Blunt dissection is performed deep to the distal aspect of the vastus lateralis to enter the plane between the lateral femoral periosteum and vastus lateralis, which is easily defined.
- The plate is then tunneled proximally along the lateral femoral periosteum (TECH FIG 3A–C).
- Slow advancement of the plate allows the surgeon to feel the plate contact against the lateral femur.

Fluoroscopy may assist the surgeon in guiding the plate past the fracture (TECH FIG 3D).
- Once the plate is fully advanced, AP and lateral views are obtained with fluoroscopy to confirm the plate position.
- A Kirschner wire is then placed percutaneously in the most proximal and distal holes using fluoroscopy to secure the plate position (TECH FIG 3E,F).
- Occasionally, adjustments need to be made to the plate position on the lateral view before Kirschner wire placement.
Screw Placement

- The principles of external fixation are used to guide the surgeon in screw placement.
- Three screws are placed proximal and three screws distal to the fracture (rarely there is room for only two screws).
- The screws should be spaced as far apart as possible on each side of the fracture.
- One of the screws should be placed near the proximal and distal margins of the fracture (TECH FIG 4A).
- No lag screws are used as the fracture region is bridged.
- Freehand “perfect circle” technique is used for percutaneous screw placement.
- With fluoroscopy in the lateral position, the holes in the plate are visualized as a “perfect circle” to guide the drill.
- A stab incision is made over the “perfect circle” and the knife blade is directed horizontal to the fluoroscopic beam through the iliobial band and vastus lateralis to the desired hole.
- The 3.2-mm drill bit is then placed into the desired hole and the surgeon drills perpendicular to the plate through both cortices.
- The fluoroscopic image is rotated to the AP view.
- The depth gauge is placed on the anterior thigh, and fluoroscopic imaging is used to obtain the appropriate screw length.
- A Vicryl suture is tied over the screw head so the screw capture into the screwdriver is not lost during percutaneous screw placement (TECH FIG 4B–E).
- The decision as to which percutaneous screw to place first is determined by where the femur is furthest from the plate and closest to the fracture.
- The screw will act as a reduction screw, reducing the femur to the plate contour (TECH FIG 4F,G).
- The second screw is placed on the opposite side of the fracture.
- The remaining screws are then placed, attempting to achieve the greatest screw spread possible to achieve maximal stability.
- Once the plate has been fixed to the femur, final radiographs are obtained to ensure adequate alignment and length (TECH FIG 4H,I).
- The Vicryl ties are cut and the incisions are closed.

**TECH FIG 4** • A. Fluoroscopic image of two screws bridging the fracture. These are commonly the first two screws placed. They are on the proximal and distal margin of the fracture. B–E. Percutaneous screw placement using fluoroscopic guidance and “perfect circle” freehand technique. B. The scalpel localizing the position and forming a percutaneous incision to the desired screw hole. C. Drilling a bicortical screw hole. D. An absorbable suture is tied around the screw head. E. Percutaneous screw placement. F,G. Reduction of the femur to the precontoured plate using the screw for reduction. H,I. Postoperative AP radiographs of the long oblique proximal-third femur fracture managed with the submuscular plate.
PEARLS AND PITFALLS

- A provisional reduction should be obtained with traction to restore fracture length and rotation.
- The surgeon should make sure rotation is correct using fluoroscopy and fracture geometry before plating.
- The correct plate length is one that spans from just below the greater trochanteric apophysis to the distal femoral metaphysis.
- The plate is temporarily secured to the femur with a Kirschner wire placed in the proximal and distal screw holes. Plate position is confirmed with fluoroscopy before screw placement.
- Three screws proximal and three screws distal to the fracture are placed.
- The screws should be kept spaced as far apart as possible.
- The first screw placed is used to reduce the femur to the plate.
- An absorbable suture is tied around the screw to keep it from being lost in the soft tissue with percutaneous placement.

POSTOPERATIVE CARE

- A soft dressing is applied.
- A knee immobilizer can be used for postoperative comfort with mobilization.
- No bracing or casting is required in the postoperative period.
- Patients are then allowed to perform hip and knee range of motion as tolerated.
- Touch-down weight bearing is encouraged until fracture callus is seen (about 6 to 8 weeks).
- Full activity, including sports, is allowed when a bridging callus is present on at least three of the four cortices.
- Plate removal is at the discretion of the surgeon and family.
  - Removal is often recommended in the younger child with the potential for bony overgrowth of the plate.
  - If plate removal is chosen, it is recommended at 6 to 8 months.
  - If the plate is removed at a later date it will be more difficult to remove in a percutaneous manner secondary to tissue overgrowth.
- The plate can be removed through the same percutaneous incisions.
  - A Cobb elevator is advanced proximally along the lateral aspect of the plate to free the soft tissue.
  - The screws are then percutaneously removed using fluoroscopy.
  - A Cobb elevator is then placed between the plate and bone to free the plate to allow removal through the distal incision.

OUTCOMES

- Over the past 30 years, femur fracture plating has evolved in terms of the use of longer plates, indirect reduction techniques, fewer plate screws, and fewer lag screws.
- The best predictor of success is the length of the plate.9
  - In comminuted and long oblique fractures treated with submuscular plating, the longer plate results in less strain on the healing fracture.
- Since the comminuted fracture is spanned with a long plate, the strain on the healing fracture is less.
- With the soft tissues intact around the fracture, the more rapid callus formation results in earlier load-sharing of the bone with the plate.
- This limits the period of the load carried by the plate and the potential for failure.
- The longer plate also requires fewer screws for optimal plate fixation.

- There is a subgroup of pediatric femur fractures in which the options for treatment are complex.
  - This encompasses the comminuted and long oblique length unstable fracture, the larger adolescent, and more proximal and distal fractures.
  - Complications have been reported while treating these complex fractures with other methods of fixation, such as titanium elastic nails or external fixation.3,8,11
  - In comparison, the published results of submuscular plating are very successful, with minimal reported complications.1,6,10
  - Submuscular bridge plating is a reliable and predictable method to stabilize the more complicated pediatric femur fracture.

COMPLICATIONS

- Reported complications are rare, and there are only two currently reported: refracture after early plate removal and a 3.5-mm plate that bent.6
  - These reported complications can be avoided by waiting for complete healing before plate removal and using a 4.5-mm plate in all but the smallest femurs.
- Since the fracture is secured out to length, there is the potential for postfracture femoral overgrowth.
  - In our experience, this potential overgrowth does not become clinically relevant.
  - There is a loss of anterior bow or a few degrees of recurvatum in many fractures after union, but again this has not been proved to be clinically relevant.
- Appropriate plate bending can help prevent malunion.

REFERENCES

DEFINITION
- Distal femoral physeal fractures involve the femoral condyles distal to the physis.
- The fractures may be extra-articular (Salter-Harris types I and II fractures), which are also referred to as distal femoral physeal separations. The fractures may also be intra-articular (Salter-Harris types III and IV) (FIG 1).¹
- The important things to assess are involvement of the distal femoral growth plate and articular congruity.

ANATOMY
- The distal femoral physis is one of the fastest-growing and most important growth plates of the lower extremity (FIG 2). The physis is remarkable for its multiple undulations.
- The medial and lateral collateral ligaments originate from the medial and lateral condyles.
- The anterior and posterior cruciate ligaments originate in the intracondylar notch.
- The peroneal nerve and popliteal artery are close by.

PATHOGENESIS
- A direct blow to the knee from medial or lateral may result in avulsion of the distal femoral epiphysis in whole or in part. The distal femoral condylar unit may displace medially or laterally.
- A hyperextension injury of the knee may result in distal femoral physeal separation with anterior displacement of the femoral condylar unit.
- A direct blow to the flexed knee (dashboard injury) may result in fracturing of the distal femoral epiphysis in a variety of patterns, including the Salter-Harris type IV fracture.

NATURAL HISTORY
- While most physeal separations (Salter-Harris type I and II fractures) have an excellent prognosis for healing without growth derangement, fractures of the distal femur are more prone to result in growth problems.
- This may result from “shaving off” of the undulations of the growth plate or from “scuffing” of the growth plate by the metaphysis during displacement and replacement of the epiphysis.⁴
- Because this growth plate is rapidly growing and makes an important contribution to the total length of the limb, any derangement here is likely to become symptomatic.²,³,⁴
- Parents must be warned of the possibility of growth derangement (shortening or angular deformity) as a result of physeal damage.
- Healing problems and joint stiffness are unlikely.

PATIENT HISTORY AND PHYSICAL FINDINGS
- A history is necessary to reveal the direction and magnitude of the injuring force.
- Pulses and neural function must be routinely assessed.
- Inspection often reveals that the knee is swollen; it may even appear dislocated (FIG 3).
- The degree of displacement correlates with the degree of deformity.
- True knee dislocation is uncommon in the immature patient; distal femoral physeal separation is not.
- The clinician should perform a varus–valgus stress test. Apparent instability suggests that radiographs (with and without stress) should be obtained to differentiate separation from ligament injury.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- Plain film anteroposterior (AP) and lateral radiographs of the distal femur or knee should be obtained (FIG 4A,B).
- Truly undisplaced separations may be visualized on stress radiographs (FIG 4C,D).
- Displaced intra-articular fractures should be visualized by CT scanning (FIG 4E-H).
- If there is suspicion of concomitant intra-articular derangement, MRI should be obtained before the insertion of metallic hardware.
Chapter 15

DISTAL FEMORAL PHYSEAL FRACTURES

FIG 2 • A. AP diagram of knee with physis, collateral ligaments, and cruciate ligaments. B. Lateral diagram of knee with cruciate ligaments.

DIFFERENTIAL DIAGNOSIS
- Dislocation of knee
- Dislocation of patella
- Proximal tibial fracture
- Fracture of distal femoral metaphysis

FIG 3 • Picture of swollen knee.

NONOPERATIVE MANAGEMENT
- Truly undisplaced fractures can be immobilized in a long-leg cast.
- Fractures should be re-evaluated by radiography in a few days to check for displacement.
- Fractures that are easily reducible are rarely stable and are not amenable to simple cast immobilization.3

SURGICAL MANAGEMENT
- Surgical management should be considered for displaced or irreducible distal femoral physeal separations (Salter-Harris type I or II).
- Surgical management should be considered for displaced or unstable intra-articular fractures (Salter-Harris type III or IV).

■ Surgical management should be considered for fractures associated with nerve, vascular, or soft tissue injuries that would preclude standard casting.

Preoperative Planning
■ If manipulative reduction is contemplated, the surgeon should request muscle relaxation from the anesthesia provider after induction.
■ If distal pulses are diminished before fracture reduction, provision should be made for vascular surgical consultation if the normal pulse is not restored after reduction.
■ The distal femur must be visualized in AP and lateral views on fluoroscopy.
■ Intra-articular fractures should be studied by CT scan preoperatively. Fractures that are simply separated may be amenable to percutaneous lag-screw fixation. Fractures that are widely displaced or rotated may require open reduction and internal fixation.

Positioning
■ Generally patients can be positioned supine on a radiolucent table. However, fractures that are displaced into extension may be best fixed with the knee flexed over a bolster (FIG 5).

Approach
■ Distal femoral physeal separations will generally be managed by closed reduction and percutaneous fixation.
■ Fractures that cannot be reduced closed should be managed with open reduction, with the surgical approach on the side (medial or lateral) where the periosteum is torn.
■ Salter-Harris type I and I fractures with a small Thurston Holland fragment should be fixed with smooth pins across the physi.
■ Salter-Harris type II fractures with large Thurston Holland fragments should be fixed with transverse screws that lag the Thurston Holland fragment to the metaphysis.
■ Salter-Harris type III and IV fractures should be anatomically reduced and fixed with lag screws.

CLOSED REDUCTION AND PERCUTANEOUS PINNING

Fracture Reduction
■ Reduction should be done as soon as possible and certainly within a week of injury or the fracture may not be reducible.
■ Optimal anesthetic technique includes maximum muscle relaxation before fracture reduction.
■ Extension injuries are best reduced with the knee in flexion (TECH FIG 1).
■ Separations displaced medially or laterally are reduced by a medial or lateral force opposite to the direction of displacement.

Fixation
■ Smooth Kirschner wires are placed under fluoroscopic control after reduction of the fracture. Stout wires should be used (greater than 2 mm in diameter). Two pins are used.
■ One starts in the medial epiphysis and is advanced across the separation out the medial femoral metaphysis (TECH FIG 2A–C).
The second starts in the lateral epiphysis and is advanced across the separation into the lateral metaphysis (TECH FIG 2D,E).
- Pins left protruding distally may provide a portal to seed the knee joint with bacteria. For this reason, consideration should be given to advancing the pins proximally out the contralateral metaphysis and out the skin of the thigh. The pins are grasped proximally and drilled retrograde until the distal end disappears into the knee joint and the epiphysis of the distal femur. Pins are left protruding proximally (TECH FIG 2F).
- A cast or splint is applied with the knee in a comfortable degree of flexion.

**CLOSED REDUCTION AND PERCUTANEOUS SCREW FIXATION**
- This technique is satisfactory for type II epiphyseal separations with a substantial Thurston Holland fragment or for type III and IV fractures that are not widely displaced or rotated.
- The fracture is reduced by closed manipulation (TECH FIG 3A,B). Guidewires for cannulated screws (usually 4.5 mm) are passed percutaneously using fluoroscopic guidance. The guidewires should be passed perpendicular to the plane of the fracture and parallel to the physis (TECH FIG 3C).
- Fluoroscopy confirms wire placement. Overdrilling precedes placement of lag screws (TECH FIG 3D). Generally two screws are placed (TECH FIG 3E).
- Stability of fixation is tested. Hardware is added if needed.
- A splint or cast is applied.
OPEN REDUCTION AND INTERNAL FIXATION

Extra-articular Fractures
- A tourniquet should be applied to the thigh and inflated after exsanguination.
- Irreducible epiphyseal separations should be approached from the side on which the periosteum is torn (TECH FIG 4A).
- An incision is made medially or laterally over the physis. Interposed soft tissue, usually periosteum, is removed and the fracture is reduced (TECH FIG 4B).

Intra-articular Fractures
- Fixation is then placed as for the above procedures (TECH FIG 4C).

Fixation is then placed as for the above procedures (TECH FIG 4C).

Intra-articular Fractures
- Salter-Harris type III or IV fractures that cannot be reduced closed should be approached by a parapatellar arthrotomy on the same side of the fracture.
- Hematoma is evacuated.
- The fracture is reduced under direct vision and lagged in place with cannulated screws (TECH FIG 5).
- Closure and splinting or casting are routine.
PEAKS AND PITFALLS

| Indications | Fractures that present late (more than 7 to 10 days after injury) may be irreducible. These should be left to heal. Late osteotomy can be performed if necessary. |
| Nerve and vascular injury | Specific examination for distal pulses and peroneal nerve function is necessary before treatment. |
| Pin placement | When drilling pins retrograde, it is important to avoid the nerve and vascular structures in the posterior aspect of the distal thigh. |
| Pin tracts | Tension in skin around pin tracts should be relieved before immobilization to prevent problems with pin tract irritation. |

POSTOPERATIVE CARE

- The splint or cast is left for 1 month.
- Straight-leg raising is encouraged.
- Weight bearing is not allowed.
- Pins are pulled at cast removal.
- Motion is allowed after cast removal.
- Screw removal is optional after complete healing.

OUTCOMES

- Healing is not a problem and can be expected in all cases.
- The knee will be stiff when the cast is removed, but range of motion is usually quick to return.
- Up to one third of patients may develop late growth derangement. Assessment of the physis with plain radiographs and in most cases MRI is important because the rate of growth arrest is so high. An MRI at 4 to 6 months may show the first signs of physeal arrest.

COMPLICATIONS

- Nerve or vessel injury
- Malreduction
- Pin tract infection
- Growth derangement

REFERENCES

DEFINITION
- Fractures of the tibia are common in children.
- Severity ranges from nondisplaced “toddler’s” fracture to high-energy open injury.
- Open growth plates at the ends of the tibia preclude standard adult treatment options such as solid interlocked nails.
- Many cases can be managed nonoperatively, but orthopaedists need to maintain familiarity with operative techniques.

ANATOMY
- Relevant anatomy includes muscle compartments (anterior, posterior, superficial and deep posterior), cross-sectional shape, and growth plates (FIG 1).
- Neurovascular structures are at risk from direct trauma or compartment syndrome.
- Understanding the anatomy of the growth plates is crucial when planning fixation techniques.

PATHOGENESIS
- The most common injury scenarios are either low-energy injuries, such as those sustained during sports (twisting injury), or high-energy ones, such as seen in car-versus-pedestrian accidents (direct blow, comminuted fracture).
- Many injuries fall somewhere along the spectrum.
- High-energy injuries often are seen with concomitant injuries, such as ipsilateral femoral injuries (the so-called floating knee), compartment syndromes, and intra-articular injuries of the proximal or distal tibia.
- Occasionally, the fracture may be pathologic through an underlying bone lesion (eg, nonossifying fibroma, aneurysmal bone cyst, osteomyelitis, osteosarcoma).
- As in all fractures in young children, child abuse must be suspected if the history is unclear or multiple fractures are present.

NATURAL HISTORY
- Because of the significant remodeling potential in young children, most patients heal without sequelae.
- Morbidity from associated injuries, however, may be significant (ie, compartment syndrome), so a thorough evaluation is of paramount importance.
- General guidelines are available to define acceptable healing alignment (Table 1).

PATIENT HISTORY AND PHYSICAL FINDINGS
- The history should include mechanism of injury, antecedent pain, neurologic symptoms, and other areas of pain (eg, femur, abdominal pain, headache).
- A high-energy injury should also prompt a full trauma workup using standard Advanced Trauma Life Support protocols.

FIG 1 • A. Cross-sectional anatomy at the midtibial level. Note the triangular shape of the tibial shaft; this is important when placing external fixator pins. B. Arterial supply of the leg viewed from posteriorly. The anterior tibial artery penetrates the interosseous membrane proximally and is tethered there, putting it at risk for injury in proximal fractures. C. Proximal tibial physis viewed laterally. It is important to appreciate the continuity of the tubercle and proximal tibial growth plates. Injury to the tubercle growth plate will result in a recurvatum deformity.
Fractures of the Tibia

Curso: 

Computed tomography can be helpful to assess these regions.

For complex fractures, dedicated knee and ankle films can be helpful to evaluate for extension into the physeal or articular regions.

Computed tomography can be helpful to assess these regions if radiographs do not provide sufficient clarity.

Contralateral full-length films are helpful for determining length in comminuted fractures.

STUDIES

Compartment pressure measurements should be obtained in cases of concern (Figure 1A). Compartment syndrome is signaled by tense swelling of the compartment, pain with gentle squeezing of the compartment, pain with passive extension–flexion of toes, and paresthesias in involved nerve distributions. Loss of pulse is a late finding.

Patients with any of these signs should be considered at risk. A low threshold should be present for measuring compartment pressures and performing fasciotomy as needed. Vigilance is required to prevent permanent sequelae due to missed compartment syndrome.

IMAGING AND OTHER DIAGNOSTIC STUDIES

The physical examination should focus on assessing initial displacement and skin condition (ie, open injury), as well as swelling of the compartments.

The limb should be splinted, in the case of gross deformity, before obtaining films using material that permits high-quality radiographs.

A thorough neurovascular examination is needed to assess for vascular injury or compartment syndrome.

Pulses should be palpated or obtained with Doppler assistance.

Sensation in the deep and superficial peroneal nerve and tibial nerve distributions should be assessed, as well as motor function (toe flexors–extensors).

Pain with passive motion of the toes may represent an evolving compartment syndrome. More specifically, increasing pain, or pain out of proportion to the injury, is often the first early warning sign and should be taken seriously. Splitting or removal of casting material should be performed if any question exists.

Compartment pressure measurements should be obtained in cases of concern (Figure 1A).

Compartment syndrome is signaled by tense swelling of the compartment, pain with gentle squeezing of the compartment, pain with passive extension–flexion of toes, and paresthesias in involved nerve distributions. Loss of pulse is a late finding.

Patients with any of these signs should be considered at risk.

A low threshold should be present for measuring compartment pressures and performing fasciotomy as needed. Vigilance is required to prevent permanent sequelae due to missed compartment syndrome.

DIFFERENTIAL DIAGNOSIS

- Isolated tibial fracture
- Floating knee
- Pathologic fracture
- Intra-articular or intraphyseal injury
- Compartment syndrome
- Child abuse

NONOPERATIVE MANAGEMENT

Most tibial fractures can be managed with closed reduction and cast immobilization in an above-the-knee cast.

The cast should be molded to the anatomy of the tibia.

A supracondylar “squeeze” mold above the knee and 15 to 20 degrees of knee flexion can prevent cast slippage.

To truly avoid weight bearing, the cast must be flexed at least 70 to 80 degrees (if appropriate for a specific fracture).

In cases of acute fracture, the cast can be univalved to allow for swelling. It can then be overwrapped before initiating weight bearing.

Weekly radiographs are obtained for the first 3 weeks, with the cast being wedged or changed as needed for loss of alignment.

Weight bearing is dictated by patient comfort.

The cast is changed to a short-leg or patellar-bearing cast after 4 to 6 weeks, and immobilization is continued until healing is complete.

Surgical management is required for inability to maintain satisfactory alignment (Table 1).

SURGICAL MANAGEMENT

Indications for surgical treatment of tibial fractures in children include open injuries, compartment syndrome, multiple injuries, and fractures for which closed treatment fails.

Treatment in mature adolescents is the same as for adults with reamed, locked nails.

Younger children’s open physes require techniques that avoid the proximal and distal tibia, such as external fixation, plate fixation, and elastic intramedullary nailing.

Traditionally, external fixation was used primarily for fractures with significant comminution or soft tissue injury, where intramedullary fixation was considered impractical. However, recent work challenges this paradigm for surgeons experienced with elastic nailing.

Rapid stabilization of the multiply injured child is often accomplished using external fixation as well.

Plate fixation is a helpful technique for fractures not amenable to elastic nail fixation.

It is particularly helpful in patients who present with late loss of reduction and require an open approach to remove callus and realign the fracture.

It is used at our institution primarily for distal-third fractures.

After successful use in the treatment of pediatric femur fractures, the elastic intramedullary nail technique has also been successfully applied to the tibia.

Preoperative Planning

Full-length radiographs of the tibia and fibula should be obtained.

Views of the contralateral side can be helpful to determine proper length in comminuted fractures.

A clinical examination of the well side can guide the surgeon in determining rotational alignment.
The choice of fixation is determined by fracture location, comminution, and soft tissue envelope (FIG 2).

Positioning
- The patient is positioned supine on the operating table (FIG 3).
- The fluoroscopy machine can be brought in from the opposite side of the table so that it is out of the surgeon’s way.
- A small bump placed under the ipsilateral hip is helpful to counter external rotation of the femur, so that the patella is pointed straight vertically.

Approach
- The approach for treatment of tibial fractures depends on the technique used.
- Elastic nails and external fixation pins are placed through stab incisions.
- Open reduction and internal fixation approaches are the same as described for adult injuries elsewhere in this text.

EXTERNAL FIXATION
- In the supine position, traction is used to roughly align the fracture.
- Pins are placed using fluoroscopic guidance to avoid the physis.
  - Particular care is required when placing the most proximal pin.
  - The tibial tubercle physis is not easily seen on the AP radiograph.
  - A lateral view is required to avoid injury to this structure and a late procurvatum deformity.
- An array of pin sizes should be available.
- Full-sized adolescents may require 5-mm pins as in adults, but smaller children require smaller pins to avoid an overly stiff construct.
- Four-millimeter pins should be used for younger children (ie, under 10 years old), and I have found an adult wrist external fixator with 2.5-mm pins useful for treatment of toddlers with open injuries requiring fixation, such as lawnmower injuries.
- Pins are placed on each side of the fracture, one close (within several centimeters of the fracture line) and one far (at least 2 to 3 cm away from the physis).
- Children’s bone is often quite hard. Despite using “self-drilling” pins, I prefer to predrill the anterior cortex before placing the pin.
- Ring sequestra may develop from the heat generated in hard bone if pins are drilled directly in some children.
- The roughly triangular shape of the tibia should be noted (see Fig 1A).
- The pins should be started on the tip of the anterior tibia or just medial and aimed slightly medially.
- Laterally aimed pins may be unicortical, as the lateral cortex of the tibia is vertically oriented.
- The fracture is then manually reduced, using the pins for traction if necessary, and the frame is connected (TECH FIG 1A).
- In cases of soft tissue injury requiring the ankle to be immobilized, extending the frame to the first or fifth metatarsal can allow easier wound management (TECH FIG 1B).
- The pin sites are covered with iodine-soaked gauze.
  - I have caregivers begin cleaning the pin sites with half-strength hydrogen peroxide once or twice daily after the 1-week follow-up visit.
  - A posterior splint is applied to immobilize the ankle and allow soft tissue healing. It is removed after 2 to 3 weeks to begin ankle range of motion.
PLATE FIXATION

- Treatment is essentially the same as for adult injuries, but several points bear emphasis.
- It is helpful to make the incision slightly laterally over the anterior compartment so it will not lie directly over a medially placed plate (TECH FIG 2A).
- The fracture is reduced using standard techniques. Care should be taken to avoid unnecessary stripping of the fracture.
- I prefer to make an incision over the fracture large enough to reduce the fragments but not the entire length of the plate.
  - The plate can be slid under the skin, over the periosteum, and the screws placed through stab incisions, as for percutaneous plating in adults (TECH FIG 2B).
- For larger children, many adult fracture systems include precontoured 3.5-mm plates for the distal tibia.
  - For smaller children, a small fragment plate may be contoured to fit appropriately.
  - It is important to avoid injury to the perichondral ring at the distal extent of the plate.
- If the plate is applied on the medial side of the tibia, as it often is for fractures with valgus angulation, it will usually need to be removed after healing due to prominence.
- If applied laterally, I usually make a longer incision, since percutaneously placed screws will traverse the anterior compartment and potentially injure the neurovascular bundle. I prefer open placement in this case.
- The wound is closed using standard techniques. A posterior splint is applied to protect the soft tissues.

**TECH FIG 1**  • A. External fixation in a patient with a compartment syndrome. Arrows mark the proximal and distal growth plates. The proximal pins start fairly distally to avoid the tubercle physis. B. In this patient, an external fixator was used for a grade 2 open fracture treated with delayed closure. The patient also had a degloving injury requiring a flap and skin graft over the medial ankle. The frame was extended to the first metatarsal to immobilize the foot during healing. Although somewhat bulky, the “double stack” configuration of the frame allows for easy dynamization.

**TECH FIG 2**  • A. Incision for open reduction and internal fixation is made laterally over the anterior compartment, and the skin can then be mobilized to gain access to the fracture site. It is important not to incise the skin directly over the proposed location of the plate. B. Medial view of internally fixed tibia. A lag screw compresses the fragment, and the plate stops short of the physis. The skin incision is centered over the fracture to allow an accurate reduction, but the proximal and distal screws can be placed percutaneously through a medially applied plate. It is helpful to make one stab incision for every two holes, centered between them.
ELASTIC INTRAMEDULLARY NAIL FIXATION

- The surgeon begins by selecting the proper nail size. Usually nails should be 0.4 times the diameter of the tibial isthmus.
- The nails are contoured so that there is a C shape with its apex at the fracture site. This will cause cortical contact at the apex, yielding three-point fixation (proximal, cortical at fracture level, and distal).
- By contouring rods of equal diameter symmetrically, the elasticity of the nails resists deformation of the fracture, as opposed to reamed nailing, where the fracture is statically supported by the strength of the nail.

Preparation for Nail Insertion

- The nails are inserted in the tibial metaphysis.
  - The proper starting point is at least 1 cm distal to the proximal tibial physis and 2 cm posterior to the tibial tubercle physis (TECH FIG 3A,B).
  - The relevant landmarks should be identified fluoroscopically and marked on the skin (physis, tubercle, starting points) before proceeding (TECH FIG 3B).
  - The incision should be 1 to 1.5 cm long, with its most distal extent roughly 1 cm proximal to the physis.
    - This will allow an oblique passage of the nail at the correct proximal-to-distal angle.
  - A small hemostat is used to carefully spread through the tissue down to bone, and a drill sleeve and drill are placed on the bone. The drill should be 1 to 1.5 mm larger than the diameter of the nail.
  - After checking the position of the drill tip with fluoroscopy (TECH FIG 3C), a starting hole is drilled along the proposed path of the nail (TECH FIG 3D).
    - Care is taken not to drill across the tibia out the opposite cortex.

Nail Pattern and Placement

- Multiple nail patterns have been described, but the standard is one medial and one lateral nail (TECH FIG 4A,B).
  - Alternately, if soft tissue compromise precludes the use of an entry site, the first nail is bent into a C, with the second bent into an S. The apex of the more distal curve in the nail should be at the fracture site.
  - The first nail is contoured into a C shape. It should be placed on the tibia and a fluoroscopic image obtained (TECH FIG 4C,D).
    - A gentle bend is placed in the nail, centered at the fracture.
  - The nail is placed up to the fracture site under fluoroscopic guidance. Initially, it is helpful to direct the bend posteriorly, as in the passage of a guidewire for a standard reamed nail, but it is important to rotate the bend into the proper plane to prevent a recurvatum deformity (TECH FIG 4E,F).
  - The second nail is placed in the same fashion.

Fracture Reduction and Fixation

- The fracture is then manually reduced.
  - It is rarely necessary to open the fracture to obtain a reduction, as the fracture can be easily manipulated.
  - The bent tip of the nail can be used to assist in reduction as well.
  - To pass the nails across the fracture, it is helpful to consider the initial deformity of the fracture.
    - For example, if the fracture tends to lie in valgus, it may be helpful to pass the medial nail first to apply a varus force. The second nail is then directed across the fracture site.

TECH FIG 3 • A. The proper starting point for nail insertion lies at least 1 cm distal to the proximal tibial growth plate and 2 cm posterior to the tubercle physis. B. Patient undergoing elastic intramedullary nailing of the tibia. Marked on the skin are the proximal growth plate and proposed entry sites, as well as the fracture. The incision is made proximal to the line of the physis, and an oblique angle matching the final path of the nail is dissected with a hemostat down to the bone. C. After confirming the entry site radiographically, a drill is used through a guide to open the cortex 1 to 2 mm larger than the nail diameter. D. The drill starts perpendicular to the bone and is advanced distally. Care is taken not to drill into a previously placed nail or through the far cortex.
Care should be taken to stop the nails short of the distal physis and to avoid distraction at the fracture site.

When passing the nails, it is often helpful to pass them both to the level of the fracture and sequentially crossing the fracture site.

In oblique fractures, the first nail will deform the fracture and make passing the second nail difficult if the first nail is passed all the way down initially.

In simple fractures, the order of passage is less important.

**CUTTING THE NAILS AND WOUND CLOSURE**

The nails are then cut, pulling them away from the bone without exceeding the elastic modulus of the nail, so they lie against the bone after they are cut, with about 2 cm out of the bone available for removal if required at a later date.

Alternately, the nails can be withdrawn a few centimeters, cut short, and then impacted back down the tibia, again leaving 2 cm of exposed nail beyond the entry site.

This step is important, because if the nails are left too long or are bent out away from the bone, they will become symptomatic before fracture healing. This is especially true medially, where the rod is subcutaneous (TECH FIG 5).

The incisions are closed with subcuticular suture, and a posterior splint is applied to allow tissue healing.

**TECH FIG 4 • A,B.** Potential patterns of nail insertion. The standard pattern (A) entails one medial and one lateral nail. Alternately, both nails are inserted from the same side to avoid compromised skin (B). In the tibia, the former technique is far easier. C. The nail is placed on the skin, with the tip at the proposed final location, as confirmed radiographically. D. The nail is marked at the fracture site and bent to place the apex at that location. E. When starting a nail, it is helpful to rotate the nail so that the tip points anteriorly, bouncing off the posterior cortex. F. The nail is then turned so that the bend in the nail lies in the coronal plane.

**TECH FIG 5 •** Instead of cutting the nail under the skin, it can be withdrawn, cut at skin level (A), and tamped in to prevent irritation (B).
**PEARLS AND PITFALLS**

**POSTOPERATIVE CARE**

- For patients treated with external fixation, a splint is used for 7 to 10 days to allow the tissues to recover.
- For stable fractures, progressive weight bearing is initiated in reliable patients.
- Unstable or comminuted fractures require waiting until visible callus is present before weight bearing.
- Depending on fracture stability, dynamization of the fixator is initiated early, after sufficient callus is seen. The frame is removed in the office or the operating room after healing is noted radiographically.
- Most patients benefit from short-term support with a bivalved cast after removal.
- Patients treated with plate fixation begin a progressive weight-bearing program, with immobilization discontinued after sufficient radiographic healing is present, usually by 6 weeks.
- Patients treated with elastic intramedullary fixation are usually splinted for 7 to 10 days, followed by progressive weight bearing. The plan is modified based on fracture stability, soft tissue injury, and patient reliability.
- Patients with substantial (over 50%) cortical contact may begin weight bearing as tolerated after soft tissue healing has occurred.
- In general, prolonged stiffness is unusual in pediatric patients.
- It is better to overimmobilize in questionable cases to avoid malalignment and regain motion later with aggressive physiotherapy.
- Removal of symptomatic hardware (ie, nails or plate) should be delayed until fracture healing and remodeling are complete.
- I prefer to remove elastic nails electively in all patients 6 to 9 months after injury, as the nails will become completely intramedullary with significant continued growth, thus making late removal extremely difficult.
- Ideally, plate removal is delayed for a year, after remodeling is complete.

**OUTCOMES**

- Most tibial fractures in children will heal uneventfully, although healing difficulties can occur, especially in older patients.\(^4\)
- Slon\o^13 noted that most complications seen in his series were a result of improperly applied technique, particularly residual distraction at the fracture site, leading to a “pseudarthrosis model” even in children.
- Bar-On and associates\(^2\) noted increased callus formation and shorter time to union in the elastic intramedullary nailing

---

**FIG 4** Potential pitfalls in nail placement. A. The nails are of differing diameter, inducing a valgus moment that needs to be controlled in a cast. Note the incidental nonossifying fibroma. B. “Spiraling nails.” The elasticity afforded by three-point fixation is lost, making the construct less stable.
group versus external fixation (7 weeks compared with 10) in a femur model.

- Myers and coworkers\textsuperscript{10} reported a significant complication rate in high-energy tibial fractures treated with external fixation, including delayed union, malunion, leg-length discrepancies, and pin-tract infections.
- Kubiak and colleagues\textsuperscript{8} reported 2 delayed unions, 2 malunions, and 3 nonunions in a series of 15 patients managed with external fixation, although these appear to have occurred in open injuries.
- They reported higher functional scores in their patients treated with elastic intramedullary nailing compared to external fixation.
- Operative techniques usually require additional procedures for removal of pins or prominent nails or plates.
- Obviously, operative complications do not occur in nonoperatively treated patients. Knowledge of proper indications is crucial to maximize outcomes.

COMPLICATIONS

- Malunion
- Delayed union
- Leg-length discrepancy
- Compartment syndrome
- Symptomatic hardware
- Infection

REFERENCES

DEFINITION
- Tibial tuberosity fractures are relatively rare fractures in adolescents. They commonly occur in the later years of skeletal growth before physeal closure.
- The fracture mainly occurs in boys, but there are a few cases reported in girls.
- The injury occurs while jumping, such as while playing basketball.
- There may be a history of prior tuberosity apophysitis.

ANATOMY
- The tibial tubercle develops in four stages. 5
  - In the first stage the tubercle is completely cartilage before a secondary center of ossification forms.
  - The second, or apophyseal stage, occurs at age 8 to 12 years in girls and 9 to 14 years in boys. The secondary center of ossification forms, but it is not connected to the epiphysis of the proximal tibia.
  - The third, or epiphyseal, stage is when the “tongue” of the apophysis and the epiphyseal bone are continuous. The ages for the third stage are 10 to 15 years for girls and 11 to 17 years for boys.
  - In the final stage the physis is completely fused and becomes bony.
- The patellar ligament inserts into the proximal portion of the apophysis. There is a broad insertion into the periosteum distal to this. The insertion is lateral to the midline; thus, the fracture fragment is centered lateral to the midline.
  - This is important when considering the approach for intra-articular visualization.
- The anterior tibial recurrent artery may tear after a displaced fracture. Bleeding from its proximal branches as it retracts into the anterolateral compartment may lead to compartment syndrome.

PATHOGENESIS
- The injury occurs with a forceful quadriceps contraction while the foot is fixed. There is a significant force that the quadriceps mechanism is able to generate, and this overcomes the strength of the epiphysis and the surrounding periosteum.
- The other mechanism of injury is sudden passive knee flexion while the quadriceps is contracted.
- It has been hypothesized that individuals with this fracture may have quadriceps strength that is greater than their peers. 8 Thus, the conditions for the fracture are present during jumping and in strong individuals.
- Many of the patients have pre-existing Osgood-Schlatter disease. 1,11,12
- The injury usually occurs at a time when the tuberosity is undergoing normal closure.
- There have also been reports of associated injuries such as quadriceps tendon injury, cruciate ligament tears, and meniscal injury. 1,6,7,9

PATIENT HISTORY AND PHYSICAL FINDINGS
- Patients are usually very tender, with significant swelling over the anterior proximal tibia.
- In the more displaced fractures (type II and III) there is usually no possibility of active extension against gravity. There may also be patella alta in the more displaced fractures.
- Patients with minimally displaced fractures may extend the knee, but with obvious discomfort.
- A good neurovascular examination should be performed.
- The clinician evaluates for the presence of leg compartment syndrome.
- In the acute fracture there is a sudden onset of pain and it is difficult to ambulate. This is unlike Osgood-Schlatter disease, in which the onset is more chronic and there may be radiographic findings of a chronic condition such as calcification anterior to the secondary center of ossification.

RADIOGRAPHIC FINDINGS
- Good anteroposterior (AP) and lateral radiographs are often able to make the diagnosis.
- The displacement is most obvious on the lateral radiograph. If it is a nondisplaced fracture or the separation is minimal, a contralateral comparison radiograph may help confirm the diagnosis.
- Ogden described three types: 12
  - Type I fractures are through the apophysis.
  - Type II fractures exit between the epiphysis and apophysis.
  - Type III fractures propagate into the anterior knee joint under the anterior meniscus attachments (FIG 1).

NONOPERATIVE MANAGEMENT
- Open reduction and internal fixation (ORIF) is indicated for all patients except those with completely nondisplaced fractures.
- In nondisplaced fractures where patients can perform a straight-leg raise, a long-leg cast may be used for treatment.
  - Immobilization should be for 6 to 8 weeks.
- Close radiographic follow-up is needed for the first 2 weeks to ensure the fracture does not become displaced.
- Even in the nondisplaced fractures, percutaneous screw fixation may allow earlier immobilization and prevent 6 to 8 weeks of casting.

SURGICAL MANAGEMENT
- For fractures with more displacement, open reduction and fixation with screws is recommended.
Positioning
- Patients are positioned supine with the operative leg and knee prepared free.
- The table should allow good anterior and posterior views to be obtained with fluoroscopy.
- The tourniquet can be used to keep the field dry, allowing for good visualization of the fracture fragments and the joint reduction. The tourniquet, however, may prevent the quadriceps from being freely mobilized and may make reduction more challenging.

Approach
- A midline anterior incision is made.
- The proximal extent is the midpatella and the distal aspect is a few centimeters distal to the tibial tubercle fracture bed.
- There is a significant amount of hematoma formation and torn periosteum; thus, the incision length allows the surgeon to define the appropriate anatomy and prepare the fragment for reduction.
- Since the tubercle and the fracture are on the lateral aspect of the proximal tibia, a lateral parapatellar approach will give better visualization of the fracture and intra-articular reduction.
- The lateral approach also limits any damage to the infrapatellar branch of the saphenous nerve.

DISSECTION AND FASCIOTOMY
- The large hematoma should be evacuated.
- There is commonly a long periosteal flap of the proximal tibia seen with the elevated fragment that needs to be extracted from the fracture.
- A prophylactic anterior compartment fasciotomy is performed.
- The distal, medial, and lateral extent of the fracture should be surgically defined with sharp dissection.
- For the type of fracture that exits the anterior part of the knee joint, the surgeon must visualize the knee joint. This can be accomplished by looking into the knee through the fracture or by a parapatellar approach. Specifically, the surgeon must ensure the meniscus is not injured or interposed in the fracture before reduction.

OPEN REDUCTION
- Next, the fracture is reduced; this is aided by leg extension.
- Often the articular surface can be first reduced and the distal aspect then reduced into the base.
- Reduction is confirmed with both visualization and fluoroscopy.
- If the fracture is not reduced anatomically, it is due to soft tissue interposition or meniscal interposition (TECH FIG 1).

TECH FIG 1 • A. A 15-year-old boy with a displaced tibial tuberosity fracture that enters the joint surface. B. Initial postoperative lateral radiograph after open reduction and internal fixation. Despite initial fluoroscopic views indicating an adequate reduction, the radiographs indicate a poor reduction. (continued)
Once the fracture is reduced, screw fixation is recommended. Provisional Kirschner wires may be placed to hold the reduction before screw fixation. The screws are placed from anterior to posterior parallel to the joint surface. Bicortical purchase is not imperative due to the thin posterior cortex in this region. It is important to prevent vascular injury posterior to the knee joint in this region. Cancellous screws in compression are ideal for this location. Cortical screws will achieve fixation as well, especially more distal.

If there is a large bone fragment, two or three 4.5-mm screws are ideal and may lead to less screw head irritation (TECH FIG 2A,B). We often use a washer for the thinner cortical bone at the distal region of the fracture. Alternatively, 6.5- or 7.3-mm screws can be used, although screw head irritation may occur. The surgeon should avoid placing the screws directly under the incision (TECH FIG 2C).
POSTOPERATIVE MANAGEMENT

- Postoperatively, a cylinder cast for 4 weeks is commonly used, followed by progressive range of motion, or a knee immobilizer for 4 weeks, followed by range of motion.
- Postoperative immobilization depends on the fixation. Smaller bone fragments will likely require more immobilization than larger bone fragments, where greater fixation can be achieved.

OUTCOMES

- Most of the published series have a small number of patients, due to the rare nature of this fracture.
- All studies have been consistent in their conclusion that the fractures heal with success and patients return to normal function. Growth abnormality has not been reported.4,9,11,12

COMPLICATIONS

- Reported complications are few for the tibial tuberosity fracture. Screw prominence is the most common complication.14
- Compartment syndrome has been reported.10,13 A prophylactic anterior compartment fasciotomy and close observation and recognition may decrease the possibility of this complication.
- Growth disturbance, such as a recurvatum from tibial tubercle arrest, is not much of a concern as this fracture occurs in adolescents near the end of growth.
- Loss of motion or quadriceps muscle weakness is extremely rare but may occur with a malunion or malreduction.2

REFERENCES

DEFINITION

- Ankle fractures account for about 5% of all pediatric fractures and are second only to distal radius fractures as the most prevalent long-bone physeal fracture comprising approximately 15% of these injuries.1
- As in most pediatric trauma, nonoperative management is the mainstay of treatment; however, surgical indications can be specific to the pediatric population.
  - Surgical treatment is mandated with any significant articular incongruity as in the adult population.
  - It is our experience that physeal fractures of the distal tibia require near-anatomic alignment to prevent the complication of premature physeal closure.1,7
- Classification of pediatric ankle fractures can be a practical tool for both the treatment and prognosis of these fractures.
  - The most common classification scheme for pediatric ankle fractures is the anatomic Salter-Harris method for physeal fractures.
  - We have found the Lauge-Hansen mechanistic classification derived for adults is very useful, as this aids in conceptualizing the reduction technique by reversing the fracture pattern. Also, our data have shown that pronation-type injuries have a higher rate of premature physeal closure than the supination–external rotation type of injuries.7
  - We also find this useful as most orthopaedic surgeons are familiar with this classification.
  - Additional classification systems include the fibular-based Danis-Weber system, as well as a more comprehensive classification suggested by Dias and Tachdjian that uses the Lauge-Hansen guidelines correlated with the Salter-Harris classification.2,4
- Transitional fractures of the ankle occur near skeletal maturity and are due to the asymmetric closure of the distal tibial physis.
  - Triplane fracture is described as a complex Salter-Harris type IV fracture that consists of sagittal, transverse, and coronal components with an epiphyseal and metaphyseal fragment.
  - Tillaux fractures occur most often in adolescents within 1 year of distal tibial physeal closure. They involve an external rotational force that avulses off the anterolateral aspect of the tibial epiphysis, which is attached to the anterior tibiofibular ligament, which is stronger than the residual open physis laterally.
ANATOMY

- The ligaments of the ankle attach to the epiphyses, provide stability to the ankle mortise, can play a role in the pathomechanics of transitional fractures as the growth plate closes (triplane and Tillaux fractures), and are often more stout than the growth plate about the ankle, leading children to sustain physeal fractures more readily than ankle sprains.
  - The anteroinferior tibiofibular ligament attaches strongly to the anterolateral border of the tibial epiphysis, and with an external rotation force on the foot it has the ability to avulse off the anterior lateral fragment of the tibial epiphysis; the strength imbalance between the ligament and weaker physis can create the transitional Tillaux and triplane fractures.
  - The anatomy of the distal tibial physis is relevant to understanding certain ankle fractures and their management and prognosis.
  - The secondary ossific nucleus of the distal epiphysis appears between 6 and 24 months, with the apophysis of the medial malleolus often extending from an elongation from this ossific nucleus or from a separate ossification center, the os subtibiale, which ossifies between 7 and 8 years of age.
  - The distal tibial physis is for the most part transverse; however, there is an anterior medial undulation that consistently appears within the first 2 years of life that has been described by Kump (termed Kump’s bump). This central-medial location is where physiologic physeal closure begins (FIG 1).
  - Physeal closure of the distal tibia occurs around 15 years of age in girls and 17 years of age in boys.
  - Closure progresses from the central-medial location of Kump’s bump medially, then laterally from this location, over about 18 months.
  - The anatomy about the physis also greatly influences ankle fractures in children.
    - The perichondral ring of La Croix is a transitional area between the articular cartilage and the periosteum of the diaphysis, which is perichondrium and retains the potential for producing cartilage and bone.
    - Functionally, the perichondral ring provides stability to the physis and may play a role in certain fractures and growth plate injuries in children.

![FIG 1 • Kump’s bump. The arrow demonstrates the central-medial–located Kump’s bump, which is where physeal closure begins. We believe that damage to this structure may induce premature physeal closure.](image)
Also, this periosteum, rigidly attached to the perichondral ring, can become interposed in the fracture site and obstruct anatomic reduction.

PATHOGENESIS

- The Lauge-Hansen classification system was developed in 1950 to understand the injury mechanism by reproducing the fracture patterns in cadavers.4
- This classification is a two-part classification, with the initial portion describing the position of the foot at the time of injury (e.g., supination, pronation) and the following portion describing the direction of the deforming force; the forces are either rotational (internal or external) or translational (abduction or adduction).
- This system grades the severity of ankle injuries as I to IV in rotational patterns and I to II in translational patterns.
- In our most recent series of 114 classifiable ankle fractures (Salter II) using the Lauge-Hansen system, supination–external rotation (SER) composed 66%, abduction 30%, pronation–external rotation 3%, and axial crush injuries 1%.7
- The activity that resulted in ankle fractures varied in our series, with most occurring during falls and sports.1,7
- SER fractures did not seem to have any specific activity that was more likely to produce premature physeal closure; however, abduction injuries occurring with playing soccer or skateboarding were much more likely to develop premature physeal closure when compared to other activities.
- Specific anatomy and growth plate closure patterns create certain fractures in adolescence.
  - For example, the same external rotation mechanism can produce a Tillaux or a triplane fracture depending on the age and degree of physeal closure of the child.
  - The last portion of the distal tibial physis to close is lateral. This is often an area of weakness in the skeletally maturing child, allowing an anterolateral fragment to be avulsed from the epiphysis, creating Tillaux fractures or the fragments in the triplane fracture.

NATURAL HISTORY

- Premature physeal closure of the distal tibia has been historically described as a rare sequela in physeal fractures, with an incidence as low as 2% to 5%.1
- Our recent data demonstrate an overall 38% incidence of physeal arrest in Salter-Harris I and II fractures; however mechanism and treatment modality has been shown to affect this incidence.7
- SER injuries have a better prognosis for premature physeal closure, with a 38% overall incidence, as compared to abduction-type injuries, with a 52% overall incidence.
- In SER-type injuries the rate of premature physeal closure in patients treated without surgery was 56%; the incidence rate was only 16% in those who were treated with open reduction.
- Abduction injuries had a relatively poor prognosis for premature physeal closure whether the intervention was closed treatment (54.5% closure rate) or open treatment (50% closure rate).
- This difference in prognosis between SER and abduction injuries may be explained by the shearing force of Kump’s bump that may occur in abduction injuries, as opposed to less traumatic rotational force to this anatomic structure that occurs with SER injuries.
- These data have relevance in operative indications in pediatric ankle fractures, as an earlier series demonstrated a 3.5-fold increase in the premature physeal closure rate if a gap of 3 mm or more was present on the postreduction imaging of Salter-Harris type I and II fractures.
- Our experience suggests that periosteum interposed in the physis leads to residual fracture gapping and ultimately premature physeal closure.
- The orthopaedic surgeon should discuss the potential for premature physeal closure with the family at the initial visit, particularly with an abduction type of injury.

PATIENT HISTORY AND PHYSICAL FINDINGS

- As in adult trauma, the initial evaluation of children’s ankle injury consists of eliciting the mechanism and timing of injury.
- Basic examination should consist of evaluating the skin and soft tissues, finding areas of maximal tenderness to palpation, and obtaining an accurate sensory, motor, and vascular examination.
- Particular issues that must be considered in the diagnosis of ankle fractures in children include osteomyelitis and child abuse.
  - Osteomyelitis prevalence is 1 per 5000 children. It generally occurs in the vascular loops of the metaphyseal regions of bone in children and can occur because of hematogenous spread or as a result of trauma, which can further complicate diagnosis.
  - A good history of the proximity of pain onset relative to the inciting trauma will help differentiate trauma from infection.
  - Metaphyseal fractures of the distal tibia in children can be concerning for child abuse, as the mechanism can be attributed to forceful pulling or twisting of the extremity, fracturing the cancellous bone through the metaphysis. Additional concerns are bilateral extremity fractures and fractures at different stages of healing.
  - Visualization of the skin is critical in evaluation for potential open injuries. The quality of skin can also affect the timing of surgical fixation and give insight into the energy and location of injury.
  - Palpation of the ankle can assist in locating the injury and may allow diagnosis of occult physeal fractures or ligamentous injuries not seen on radiographs.
  - Establishing preoperative deficits is critical in their postoperative management and aids in establishing the need to release the extensor retinacular compartment.
  - In ankle injuries preoperative deficits can be due to nerve contusion or laceration, in addition to tendon disruption or mechanical block. This can affect the surgical approach.
  - Vascular status is the key to the ultimate viability of the extremity. If deficits are found, the fracture should be immediately reduced. If a deficit is still present after reduction, a vascular study may be considered versus immediate operative exploration to evaluate for transient spasm or vascular injury.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- If there is any suspicion of an ankle injury, a complete plain radiographic ankle series should be performed. This consists of anteroposterior (AP), lateral, and mortise views (FIG 2A–C).
  - The mortise view is critical and is taken from anterior to posterior with the foot internally rotated 20 degrees to view
the talus with a symmetric clear space seen medially and laterally.

- The importance of the mortise view is seen in Tillaux fractures, where the anterior lateral fragment is often obscured by the overlap of the posterior fibula on the AP view and is not well visualized on the lateral view.
- We do not advocate stress radiographs in children; however, we will use an external rotation stress view intraoperatively to evaluate for syndesmosis injury if suspected in children near skeletal maturity.
- Accessory ossicles can be commonly visualized on plain radiographs and may be confused with ankle fractures.
  - These include the os subtibiale medially (up to 20% of population), the os trigonum posteriorly (about 10% of population), and the os fibulare laterally (about 1% of population).
  - Contralateral comparison films may be helpful to differentiate accessory ossicles from a fracture.
- Computed tomography (CT) is required to fully understand many ankle fractures, and we often advocate three-dimensional postreduction CT scans (FIG 2D–G).
- We advocate CT scans for intra-articular fractures that show any evidence of displacement on plain radiographs, and we routinely obtain three-dimensional CT scans for triflare and many Tillaux fractures after attempted closed reduction.
- For any physeal fracture with apparent displacement in children with greater than 2 years of growth remaining, we advocate CT scanning of the ankle to evaluate for displacement, as we recommend operative treatment for trapped periostem with greater than 2 mm of displacement.
- At time of injury for Salter-Harris type I, II, and triflare fractures of the distal tibia, we also obtain plain radiographs, with an AP view of the left hand to establish bone age and AP and lateral views of the contralateral ankle for a baseline for physeal maturity and physeal comparison.

**DIFFERENTIAL DIAGNOSIS**

- Ankle sprain
- Accessory ossicle
- Osteochondral lesion (osteochondritis dissecans)
- Contusion
- Osteomyelitis

**NONOPERATIVE MANAGEMENT**

- Our clinical pathway for surgery advocates all closed ankle fractures have an attempt of closed reduction under conscious sedation in the emergency department.
- Reductions generally take place in our emergency department with the use of ketamine for conscious sedation and the aid of a portable image intensifier.
- Reduction maneuvers should reverse the established mechanism of injury derived from patient history and fracture pattern, such as the Quigley maneuver for the abduction-external rotation type of fractures.
- All our children are placed in fiberglass casts that are initially univalved with plastic spacers inserted in the cast to accommodate for swelling (FIG 3).
- In children with a high-energy mechanism or with any neurovascular change that has not improved after reduction, admission for serial neurovascular checks to monitor for compartment syndrome is recommended.
- For Salter-Harris type I, II, and triflare fractures, if a near-anatomic reduction is obtained with 2 mm or less of residual displacement, we will proceed to a long-leg cast and non-weight bearing for 4 weeks with periodic radiographs, with the frequency depending on the stability of the fracture pattern.
- To assess residual displacement in both the physis and articular surface, CT scan provides more accurate anatomic assessment, and we routinely perform plain radiographs and CT scans after reduction.
For physeal fractures that do not attain this reduction tolerance, we advocate closed reduction under general anesthesia. If we do not meet our less-than-2-mm-displacement tolerance, we proceed to perform open reduction and internal fixation in children with more than 2 years of growth remaining.

In children close to skeletal maturity, we will accept a less anatomic reduction of the physis, but not the joint.

For children with any residual intra-articular irregularity, we will generally obtain a CT scan, and if we feel we can improve on the anatomic alignment, we will proceed with open reduction and internal fixation.

SURGICAL MANAGEMENT

Preoperative Planning

A repeat attempt at closed reduction may be made in the operating room under general anesthesia in many ankle fractures to see if the fracture would be amenable to closed reduction and casting, or closed reduction and percutaneous pinning.

CT scanning with three-dimensional reconstructions now allows the surgeon to truly understand ankle fracture pathoanatomy beyond our previous abilities. We feel these studies are essential in preoperative planning in many complex ankle fractures, especially triplane fractures.

Evaluation of the CT scan allows understanding of the complex configuration of these fractures and ultimately allows the planning for lag screw placement in relation to the fracture planes.

As mentioned previously, CT scans are also important in assessment of the need for open reduction of the fracture due to gapping of the growth plate.

For the most part, in children with open growth plates, transphyseal fixation should involve only smooth Kirschner wires; screws may be used, positioned parallel to the physis.

Positioning

Almost all ankle fractures can be addressed in the supine position.

If lateral ankle exposure is necessary, a bump can be placed underneath the operative hip to improve lateral visualization.

The image intensifier is positioned with the screen at the foot of the table angled toward the surgeon on the operative side, while the C-arm should come in directly from the opposite side of the operative ankle.

The operative leg can be elevated with blankets or a foam pad to allow a pull-through lateral view unobstructed by the contralateral extremity.

Nonsterile tourniquets are applied as proximal as possible before sterile draping.

Approach

The anterior approach involves an incision of about 8 to 10 cm over the distal tibia.

The superficial peroneal nerve lies over the ankle retinaculum at this level and should be avoided.

The superior extensor retinaculum is incised at the interval between the extensor digitorum longus and the extensor hallucis longus.

Care is taken not to injure the neurovascular bundle consisting of the deep peroneal nerve and anterior tibial artery, which lies in this interval.

The posteromedial approach to the ankle consists of an incision about 8 to 10 cm roughly midway between the medial malleolus on the medial border of the Achilles tendon.

The deep fascial layers are incised longitudinally to expose the flexor tendons posterior to the ankle. At this level the flexor hallucis longus is the only muscle that still has muscle fibers.

Dissection is carried out along the lateral border of the flexor hallucis longus, which will still have identifiable muscle fibers at the level of the ankle, and the ankle is exposed as the flexor hallucis longus is retracted medially.

Care must be taken because the neurovascular bundle is just medial to the flexor hallucis longus; the tibial nerve is relatively large in young children compared to the tendon of the flexor digitorum longus.

The lateral approach involves an incision over the posterior margin of the fibula toward the distal end centered about the fracture site.

The short saphenous vein and the sural nerve run just posterior and inferior to the distal portion of the lateral malleolus.

The medial approach can be centered more anterior or posterior depending on the location of the medial malleolar fracture and the need to visualize the posterior tibia.

The incisions for these approaches should be centered over the malleolus longitudinally but should not be over the most prominent portion of the malleolus to prevent irritation.

Anterior to the medial malleolus run the long saphenous vein and the saphenous nerve, which should be preserved.
SALTER-HARRIS TYPE I AND II DISTAL TIBIA FRACTURES

- A standard anterior approach for the SER fractures is used as described above.
- For a medially gapped Salter Harris type II abduction injury, a medial approach is used (TECH FIG 1).
  - The approach can be made slightly more medial or lateral depending on the location of the fracture.
  - The fracture and growth plate should be identified and defined.
  - The fracture will most always be associated with a fracture hematoma.
  - The growth plate and perichondral ring should be identified and protected.
    - The physis has an identifiable white cartilaginous appearance.
  - Two Hohmann-type retractors can be placed around the distal tibia to allow for exposure.
  - Once exposure is obtained the interposed periosteum can be removed by using a Freer elevator to carefully sweep this periosteum out of the physis.
  - Care should be taken to preserve the periosteum, as it provides blood flow to aid in fracture healing and can be intimately associated with the perichondral ring.
  - The periosteum, however, may be carefully incised and radially cut to obtain adequate reduction.
  - It is our experience in children that if necessary the periosteum can be sacrificed for anatomic reduction, as nonunion and infection are much less of a problem in this population than premature physeal closure.
  - The perichondral ring should be protected as much as possible.
  - At this point, under direct visualization, the reduction is achieved and manually held in place.
  - Once the periosteum is atraumatically removed from the fracture site and physis, the reduction should be obtained without much difficulty and should be relatively stable.
  - Many Salter type II fractures can be successfully stabilized with two 0.062-inch smooth Kirschner wires.
  - The wires are placed from distal to proximal, from the anteromedial malleolus and from the anterolateral corner of the tibial epiphysis (TECH FIG 2).
TECH FIG 2 • (continued) E,F. Open reduction was obtained after failed closed reduction due to interposed periosteum in the physeal fracture. Then the fracture was stabilized with two crossed Kirschner wires placed percutaneously. G,H. At 1 year postoperatively the distal tibial physis appears open. The red arrows mark the Harris growth line, which is parallel with the physis, demonstrating symmetric growth after injury. This further supports that the tibial physis is open.

- The entry point of the percutaneous pins must be placed distally enough through the skin to enter the bone at the appropriate starting point.
- On insertion, the Kirschner wires can be directly visualized through the open incision at their appropriate entry point into bone.
- Occasionally there may be large metaphyseal fragments that may be more appropriately stabilized with one or two lagged cancellous bone screws.
- These screws should be placed proximal to the physis and perpendicular to the fracture site.
- Cannulated screws can be used, based on the surgeon’s preference.

TILLAUX FRACTURES: SALTER-HARRIS TYPE III FRACTURES

- An anterolateral approach to the ankle is used.
- This fracture can be fixed by a distal-to-proximal, and anterior-to-posterior, compressive interfragmentary cancellous screw (TECH FIG 3).
- Again, cannulated screw fixation may be used if the surgeon prefers it to the use of noncannulated screws.
- Crossing the physis is not contraindicated in this fracture pattern because by definition the medial physis is closed and complete physeal closure is imminent.

TECH FIG 3 • Tillaux fracture treatment. A,B. Tillaux fractures are often not seen clearly on plain radiographic views, and it is important to obtain a mortise view to see the fracture fragment that is obstructed by the fibula in standard AP views. C,D. CT scans often aid in fracture characterization and operative planning. E,F. These fractures are fixed with compressive interfragmentary cancellous screws across the fracture site, without concern for transphyseal fixation as these patients are always close to skeletal maturity.
MEDIAL MALLEOLAR FRACTURES: SALTER-HARRIS TYPE III AND IV FRACTURES

- If there is only a small metaphyseal fragment, these fractures may be fixed with 4.0-mm cancellous bone screws or Kirschner wires completely within the epiphysis and parallel to the physis and joint (TECH FIG 4).
  - These fractures can be treated percutaneously if anatomic reduction can be attained by closed treatment; however, a small incision can easily allow direct visualization of the reduction.

- If a larger metaphyseal fragment is present, another metaphyseal screw can be placed parallel to the physis in addition to the epiphyseal screw.
- If the patient is skeletally immature and the fracture is not amenable to intraepiphyseal fixation, Kirschner wires may be placed across the fracture site and physis for stability of the fracture and later removed.
  - This method can also be used if there is a small avulsion fragment off the medial malleolus.
- If a larger metaphyseal fragment is present, another metaphyseal screw can be placed parallel to the physis in addition to the epiphyseal screw.
- If the patient is near skeletal maturity, these fractures can be treated as in adults with two partially threaded cannulated screws placed perpendicular to the fracture site.
  - Alternatively, in this population near maturity, compression across the fracture and apophysis can be obtained with two Kirschner wires compressed by means of a tension band wire loop.
- If the patient is near skeletal maturity, these fractures can be treated as in adults with two partially threaded cannulated screws placed perpendicular to the fracture site.
  - In certain cases it has been advocated to excise and discard the metaphyseal fragment to allow improved visualization of the physis and prevent bony bridging in this area. However, we do not advocate this form of treatment.
  - We do not advocate this approach as our goal is to ultimately restore anatomic alignment.
- If it is necessary to remove this bony fragment, we will subsequently replace it after anatomic alignment is restored and the physis is atraumatically cleared of any mechanical blockages.

![Image of medial malleolar fracture fixation with epiphyseal screw](image)

**TECH FIG 4** • Medial malleolar fracture fixation with an epiphyseal screw. If there is only a small metaphyseal fragment, medial malleolar fractures can be fixed with compressive screws placed within the epiphysis, parallel to the physis. Cannulated screws can be used to help ensure the physis is not compromised.

TRIPLANE FRACTURES: SALTER-HARRIS TYPE IV FRACTURES

- Triplane fractures are typically geometrically complicated fractures that, as mentioned above, are transitional fractures that involve the distal tibial physis at the time of its asymmetric closure during the early teenage years.
- Because these fractures are typically quite complex, we advocate CT scans with three-dimensional reconstruction for visualization and surgical planning (see Fig 2).

The surgical approach depends on the complexity of the fracture: these fractures can be two-, three-, or four-part fractures (TECH FIG 5A–C).
- Growth plate disturbance is not typically a problem owing to the proximity to skeletal maturity in these patients.
- Anatomic alignment of the articular fracture at the joint surface is important in the outcomes of these patients.

![Images of triplane fractures](image)

**TECH FIG 5** • Triplane fractures can be two-part (A), three-part (B), or four-part (C) fractures, but all involve an intra-articular epiphyseal component in addition to a metaphyseal component, making them Salter-Harris type IV fractures. (continued)
Alternative Techniques

- External fixation may be a useful tool in grossly contaminated fractures or fractures with significant soft tissue compromise, such as a lawnmower injury.
  - The goals of the external fixator are to maintain length and to ensure there is no pressure on the soft tissues from bone fragments, while the soft tissues recover.
  - External fixators can be used as temporizing devices or definitive treatment.

- There are no pediatric-specific rules for external fixator application other than to avoid physeal damage by crossing the growth plate.
  - Large, medium, or even small external fixator sets may need to be available depending on the size of the child.
  - Syndesmosis injuries generally occur in the pediatric population only at or near the time of skeletal maturity; thus, these injuries can generally be treated like adult injuries.
### Pearls and Pitfalls

#### Use of CT scans
- We advocate regularly obtaining postreduction CT scans to evaluate physeal gap as well as joint space congruity; many plain radiographs may be misleading in assessing how anatomic a reduction may be.

#### Superior extensor retinaculum syndrome
- Patients presenting with severe ankle pain and swelling, hypoesthesia or anesthesia in the first dorsal web space, weakness of the extensor hallucis longus and extensor digitorum communis, and pain on passive flexion of the great toe (FIG 4) should be evaluated for superior extensor retinaculum syndrome with pressure measurement and should likely have a release of their superior extensor retinaculum to prevent ischemic changes. Untreated, the natural history of this syndrome involves a residual sensory deficit in the first dorsal web space and contracture of the extensor hallucis longus and extensor digitorum brevis.1

#### Premature physeal closure
- To attempt to mitigate this complication we have developed an algorithm:
  - Nondisplaced fractures (less than 2 mm) are casted.
  - Displaced fractures undergo closed reduction under general anesthesia or conscious sedation, then casting for 3 to 6 weeks if displacement is successfully reduced to less than 2 mm.
  - If still displaced more than 4 mm, open reduction and internal fixation is undertaken.
  - If displacement is 2 to 4 mm with less than 2 years of growth remaining, casting is undertaken.
  - If the displacement is 2 to 4 mm and the patient has at least 2 years of growth left (girls under 12 years old and boys under 14), the surgeon’s preference of open reduction and internal fixation or casting is done.
- In addition to prereduction and postreduction ankle radiographs, to direct this algorithm we routinely obtain contralateral ankle radiographs and left-hand bone age films and, if there are any questions about fracture displacement, a postreduction CT scan.
- Additionally, we follow up with patients with growth plate fractures at regular intervals until skeletal maturity.

#### Abduction injuries versus SER-type injuries
- Abduction-type injuries carry a worse prognosis, leading to premature physeal arrest in spite of treatment (open reduction versus closed treatment), whereas the prognosis for SER injuries involving the growth plate can be greatly improved by anatomic reduction. These issues should be discussed with the family preoperatively.

#### Postoperative follow-up
- For follow-up after physeal injuries we routinely obtain baseline radiographs of the contralateral ankle, and an AP view of the left hand for establishing bone age. After initial fracture management follow-up is maintained at 6-month intervals and should include bilateral ankle radiographs.
- Alignment of both the child’s ankles should be assessed while weight bearing, as malalignment can be a sequela of premature physeal closure. If closure is noted, early physeal assessment with CT scans is necessary to prevent ankle deformity and leg-length discrepancy.

---

**FIG 4** • Superior retinaculum syndrome. A. Cross-sectional view of the superior retinaculum tunnel, which may require release with displaced physeal fractures. B. Patients presenting with severe ankle pain and tenderness, hypoesthesia or anesthesia in the first dorsal web space, weakness of the extensor hallucis longus and extensor digitorum communis, and pain on passive stretch of the great toe may require release of the superior extensor retinaculum. (A: Adapted from Mubarak SJ. Extensor retinaculum syndrome of the ankle after injury to the distal tibial physis. J Bone Joint Surg Br 2002;84B:11–14.)
POSTOPERATIVE CARE

- Treatment after surgical fixation generally consists of immobilization with a short-leg cast applied in the operating room, and the patient is kept non-weight bearing for 4 weeks.
- We univalve our fiberglass casts and place plastic spacers taped in with waterproof tape to accommodate for swelling, with the patient returning in 1 week for removal of spacers and cast overwrap and tightening with fiberglass (see Fig 3).
- Four weeks postoperatively the cast is changed to a weight-bearing cast and the child is allowed to be weight bearing as tolerated for 2 or 3 more weeks with a cast shoe.
- With percutaneous pin fixation we use 0.062-inch Kirschner wires left through the skin, which are removed at the 4-week cast change.
- Physical therapy is rarely needed for range of motion in the preadolescent population as daily activity with walking often suffices to restore function. Occasionally adolescents may benefit from physical therapy for range of motion and proprioceptive conditioning.
- We advocate follow-up for at least 1 year, at 3, 6, and 12 months, then every 6 months until skeletal maturity for children with physeal injuries to monitor for premature physeal closure.
- At these follow-up visits plain radiographs should include images of the affected ankle as well as AP and lateral views of the contralateral ankle.

OUTCOMES

- As in most children’s fractures, children with ankle fractures generally fare well.
- Data on long-term follow-up are sparse. However, data for intra-articular triplane fractures have shown the importance of anatomic alignment of less than 2 mm of displacement after treatment.
- Ertl and coworkers demonstrated with a follow-up of 18 to 36 months that “residual displacement of two millimeters or more after reduction was associated with a less than optimum result unless the epiphyseal fracture was outside the primary weight-bearing area of the ankle.”
- Rapariz and colleagues, with a mean follow-up of 5 years, found that “prognosis is surprisingly good” and that “only when adequate reduction (<2 mm displacement) has not been achieved can degenerative changes be seen at long-term follow-up (>5 years).”
- Rapariz and colleagues found good functional results ubiquitously, but as in the study by Ertl and associates, the follow-up was shorter than the time that likely could predict the long-term sequela of posttraumatic arthritis.
- Both these studies stressed the need to obtain CT scans to define and characterize the fracture and the degree of displacement, as well as advocating a trial of closed reduction to obtain adequate reduction.

COMPLICATIONS

- Premature physeal closure, as mentioned above, can lead to limb-length discrepancies and malalignment, which in younger children with continued growth potential can be symptomatic and may need to be addressed surgically.
- Reflex sympathetic dystrophy or complex regional pain syndrome is a chronic pain syndrome that can develop after these ankle injuries.
- It is characterized by pain out of proportion that persists beyond a typical recovery timeframe and may also entail swelling, skin color changes, and limited range of motion.
- Treatment can include medications, therapy, psychological counseling, and sympathetic nerve blocks; in extreme cases sympathectomy or implantation of a dorsal column stimulator has been proposed.
- Arthrosis is a normal sequela from joint injury or prolonged immobilization. Generally, in the pediatric population, interventions such as physical therapy or manipulation under anesthesia are not necessary.
- Superior extensor retinaculum syndrome, as described above, can lead to residual numbness in the great toe web space and persistent pain and weakness in the toe extensors.
- Acute compartment syndrome that is untreated can lead to permanent neuromuscular damage, including weakness or altered sensibilities.
- Malunion of fractures can occur with operative or nonoperative treatment or can be a secondary consequence of premature physeal closure.
- Osteochondral injury in ankle fractures can ultimately lead to symptomatic posttraumatic osteoarthritis, and studies have demonstrated that anatomic reduction is important to prevent this complication.
- If significant chondral injury does occur in the young patient population, drilling for focal posttraumatic osteochondritis dissecans lesions can be successful. In extreme cases with osteochondral damage, osteochondral allografting can be attempted.
- Complications with casts are inherent when they are used to treat fractures.
- These complications include cast ulceration from poorly fitted or padded casts. Casts applied too tightly or not appropriately split can lead to acute compartment syndrome. Removal of casts can lead to cast saw burns, which can permanently scar children’s skin.

Elbow Arthroscopy for Panner’s Disease and Osteochondritis Dissecans

Theodore J. Ganley, Gilbert Chan, Aaron B. Heath, and J. Todd R. Lawrence

DEFINITION

Panner’s Disease

A term often used synonymously with osteochondritis dissecans (OCD) of the capitellum, Panner’s disease is a condition in which there is diminished blood supply to the developing ossific nucleus within the distal humerus chondral epiphysis in preadolescents. Those affected are typically 6 to 10 years old, and symptoms usually respond to a reduction of the offending repetitive microtrauma.

Osteochondritis Dissecans of the Capitellum

This term is used to describe the condition of compromised subchondral bone in the capitellum of adolescents, which can lead to secondary articular surface separation.

ANATOMY

The three articulations in the elbow are the ulnohumeral joint, the radiocapitellar joint, and the proximal radioulnar joint. The ulnohumeral joint is a hinge joint that allows for flexion and extension of the elbow, while the radiocapitellar and radioulnar joints are trochoid joints that allow for axial rotation and pivoting of the elbow. The capitellum articulates with the rim of the radial head throughout flexion–extension and pronation–supination. Secondary ossification centers are involved in the formation of the distal humerus, proximal radius, and ulna. The ossification center of the capitellum appears at 18 months and completely fuses by age 14. Descending extraosseous branches of the brachial artery supply the capitellum. Chondral vessels supply the osseous nucleus, which in turn supplies the chondroepiphysis.

PATHOGENESIS

It is theorized that both Panner’s disease and OCD of the capitellum result from abnormal valgus forces exerted across the radiocapitellar joint. The result of this abnormal stress on the radiocapitellar joint may depend on the age of the patient, with those exposed to the stress at a younger age (6 to 10 years) developing Panner’s disease and those exposed to the stress at a later age (10 to 17 years) developing OCD of the capitellum. The development of the lesions also depends on the limited blood supply of the capitellum, which allows for limited repair potential.

NATURAL HISTORY

With activity restriction, reossification and resolution of symptoms typically occur in Panner’s disease. The natural history of OCD is articular surface separation for patients who do restrict their activities. Even with activity modification and brief periods of immobilization, elbow OCD lesions will progress in most patients treated nonoperatively. Initially, radiographs show irregularity and fragmentation of the capitellum. Erosion, lysis, and sclerosis may be observed in later stages.

PATIENT HISTORY AND PHYSICAL FINDINGS

Early stages Patients have full motion but complain of vague aching discomfort during throwing and load-bearing activities as well as swelling at the lateral elbow. They typically have full range of motion.

Later stages: Patients complain of mechanical symptoms, including locking and catching and limited flexion and extension; palpable synovial thickening and an effusion may also be found.

IMAGING AND OTHER DIAGNOSTIC STUDIES

High-quality, standard anteroposterior (AP) and lateral radiographs of the elbow are needed to evaluate both conditions. In Panner’s disease the size of the ossific nucleus and the degree of radiolucency can be determined from the radiographs. In OCD lesions, subchondral lysis or cystic changes may be seen on radiographs (FIG 1A). MRI findings in OCD may reveal bone edema, synovitis, and loose bodies, as well as subchondral and cartilage separation (FIG 1B).

DIFFERENTIAL DIAGNOSIS

Familial OCD

Hemophilia and variants

Multiple epiphyseal dysplasia

Autoimmune vasculitis

Steroid-induced avascular necrosis

NONOPERATIVE MANAGEMENT

Treatment for Panner’s disease consists of:

- Sling for several weeks
- Cessation of all offending activity
- Range-of-motion exercises

Nonoperative treatment of OCD is reserved for cases in which the cartilage is intact. Nonoperative treatment consists of:

- Rest until symptoms resolve
Range-of-motion exercises
Follow-up radiographs through resorption and reconstitution phases prior to resumption of sport-specific exercises.

SURGICAL MANAGEMENT
- Surgical management is largely dependent on the character of the lytic lesion and the presence or absence of symptoms.
- Cartilage intact but persistent pain and swelling
  - Arthroscopic evaluation, search for loose bodies
  - Consider drilling of lesion to stimulate subchondral bone healing.

Preoperative Planning
- All imaging studies obtained before surgery should be reviewed. An MRI may be helpful to determine the extent of the lesion and the location and size of chondral or small osteochondral loose bodies in the joint.

ARTHROSCOPIC TREATMENT
- A thorough physical examination should be performed under anesthesia to note range of motion and appropriate or pathologic degrees of laxity.

Positioning
- The patient is adequately padded and placed in the lateral decubitus position.
- The involved elbow is placed over a padded bump that places the elbow in 90 degrees of flexion.
- The extremity is then properly prepared and draped in a standard manner.
- The landmarks over the elbow are marked with a marking pen (FIG 2).

Approach
- Arthroscopy-assisted mini-arthrotomy (Children’s Hospital of Philadelphia approach) is used for large to massive loose bodies and osteochondral defects.
- After the patient is positioned, prepared, and properly draped and the anatomic landmarks are identified, a 3- to 5-cm incision is carried over the capitellum. If during the course of arthroscopy a larger incision is required, then the superior and inferior arthroscopy portals can be incorporated into an incision of 1.5 cm. Deep dissection can be in the plane of the anconeus–extensor carpi ulnaris approach.
- The incision is carried down to the fascia, and the plane between the anconeus and the extensor carpi ulnaris is identified and entered.
- The joint capsule is incised to allow adequate visualization of the lesion.
- A 30-degree arthroscope is then inserted and used to view the joint surface (TECH FIG 3B). The arthroscope is placed on the outer border of the radiocapitellar joint and angled to allow a complete view of the capitellum and radiocapitellar interval.

Preoperative Planning
- All imaging studies obtained before surgery should be reviewed. An MRI may be helpful to determine the extent of the lesion and the location and size of chondral or small osteochondral loose bodies in the joint.

ARTHROSCOPIC TREATMENT
- The patient is positioned, prepared, and draped in a lateral decubitus position as previously described.
- After the landmarks in the elbow are drawn with a marking pen and the tourniquet is inflated, 15 to 25 mL of sterile saline is injected into the joint, depending on the size of the patient.
- A smaller set of instruments (2.9 mm) is used (TECH FIG 1A).
- The arthroscopic portals are identified (TECH FIG 1B).

Preoperative Planning
- All imaging studies obtained before surgery should be reviewed. An MRI may be helpful to determine the extent of the lesion and the location and size of chondral or small osteochondral loose bodies in the joint.

ARTHROSCOPIC TREATMENT
- The patient is positioned, prepared, and draped in a lateral decubitus position as previously described.
- After the landmarks in the elbow are drawn with a marking pen and the tourniquet is inflated, 15 to 25 mL of sterile saline is injected into the joint, depending on the size of the patient.
- A smaller set of instruments (2.9 mm) is used (TECH FIG 1A).
- The arthroscopic portals are identified (TECH FIG 1B).

Positioning
- The patient is adequately padded and placed in the lateral decubitus position.
- The involved elbow is placed over a padded bump that places the elbow in 90 degrees of flexion.
- The extremity is then properly prepared and draped in a standard manner.
- The landmarks over the elbow are marked with a marking pen (FIG 2).

Approach
- Arthroscopy-assisted mini-arthrotomy (Children’s Hospital of Philadelphia approach) is used for large to massive loose bodies and osteochondral defects.
- After the patient is positioned, prepared, and properly draped and the anatomic landmarks are identified, a 3- to 5-cm incision is carried over the capitellum. If during the course of arthroscopy a larger incision is required, then the superior and inferior arthroscopy portals can be incorporated into an incision of 1.5 cm. Deep dissection can be in the plane of the anconeus–extensor carpi ulnaris approach.
- The incision is carried down to the fascia, and the plane between the anconeus and the extensor carpi ulnaris is identified and entered.
- The joint capsule is incised to allow adequate visualization of the lesion.
- A 30-degree arthroscope is then inserted and used to view the joint surface (TECH FIG 3B). The arthroscope is placed on the outer border of the radiocapitellar joint and angled to allow a complete view of the capitellum and radiocapitellar interval.
Definitive management depends on the intraoperative findings.

**Cartilage Intact**
- Drilling of the lesion is performed to stimulate healing.
- A 0.62 or 0.45 Kirschner wire is used to drill into the subchondral bone. Drilling is performed as perpendicular to the capitellum as possible, in a distal-to-proximal direction. The Kirschner wire may be placed through the inferior portal or via an inferior percutaneous approach.

**Cartilage Fractured**
- After thorough inspection of the joint is performed, any loose bodies found within the joint are removed (TECH FIG 2A,B).
- After satisfactory bleeding is obtained, final inspection of the area is performed and the arthroscope is removed and the wounds are closed using no. 4-0 Monocryl subcuticular sutures, followed by Steri-Strips.
- A sterile dressing and a posterior splint are applied.

**Techniques**

**TECH FIG 1**
- A. A smaller set of instrumentation is used.
- B. The arthroscopic portals are identified.
- C,D. The arthroscope is placed through the lateral portal, and a needle can be used as both an outflow portal (arrow in C) and as an instrument to secure loose bodies to prevent them from migrating (arrow in D).
- E. The osteochondral defect of the capitellum (above) is identified along with the radial head (below).

**TECH FIG 2**
- A,B. Loose bodies within the joint are identified and removed.
- C-E. Débridement of the defect is performed until a stable chondral rim is noted.
- F,G. Drilling is performed with a 0.62 Kirschner wire. At times it is helpful to place the wire percutaneously and flex the elbow to ensure that it is always placed perpendicular to the surface of the capitellum. Care is taken to use a posterior starting point to avoid the posterior interosseous nerve.
The defect is identified and curettage of the defect is performed to remove all granulation tissue and to ensure that a stable rim of cartilage exists circumferentially (TECH FIG 2C–E).

The underlying sclerotic bone is exposed.

Drilling of the lesion is performed using a 0.62 or 0.45 Kirschner wire. Drilling is performed as perpendicular to the capitellum as possible, in a distal-to-proximal direction (TECH FIG 2F,G).

Final inspection of the area is performed and the arthroscope is removed and the wounds are closed using no. 4-0 Monocryl subcuticular sutures, followed by Steri-Strips.

A sterile dressing and a posterior splint are applied.

**TECH FIG 3** • A. For massive lesions and loose bodies, a mini-arthrotomy can be performed through the plane of the anconeus and extensor carpi ulnaris. B,C. A 30-degree arthroscope is inserted and the lesion is identified. When a mini-arthrotomy is performed, the arthroscope can be used like a dental mirror to enhance visualization and minimize the need for extensive open dissection. D. Arthroscopic image of the elbow demonstrating an uncontained lesion treated with multiple osteochondral grafts.

**ARTHROSCOPIC-ASSISTED MINI-ARTHROTOMY**

- The patient is properly positioned, prepared, and draped as previously described.
- The mini-arthrotomy approach is carried through the plane of the anconeus and extensor carpi ulnaris. The capsule is incised to access the lesion (TECH FIG 3A).7
- A 30-degree arthroscope is inserted through the arthrotomy site to view and assess the entire lesion (TECH FIG 3B,C).
- The arthroscope can be used to assess the portions of the capitellum not clearly visualized through the arthrotomy site, much like a dental mirror.
- Once the entire lesion is visualized and assessed, removal of any loose bodies is performed with débridement and drilling of the lesion with Kirschner wires as described in the arthroscopic technique. For massive or uncontained lesions, osteochondral grafting can be performed (TECH FIG 3D).
- Final inspection of the area is performed and the arthroscope is removed.
- The capsule is repaired. A layer-by-layer closure is then performed (TECH FIG 3D).
- A sterile dressing is applied and a posterior splint are applied.

**PEARLS AND PITFALLS**

POSTOPERATIVE CARE

- For full-thickness defects, immediate continuous passive motion and physical therapy are started for 6 weeks.
- After 6 weeks, a gradual return to activity is instituted. Strengthening and range of motion are still the main goals of therapy. Axial loading, impact loading, and throwing are prohibited for up to 6 months.

OUTCOMES

- Panner’s disease
  - Full recovery is expected in 12 to 18 months, but long-term noncompliance can result in lesion progression.
- OCD of the capitellum
  - Ruch and coworkers\(^8\) reported on 12 patients treated for OCD of the capitellum by arthroscopic débridement; 11 of them were highly satisfied. The average age was 14.5 years and the average follow-up was 3.2 years. Clinical presentation showed a contracture improvement from 23 degrees to 10 degrees.
  - Byrd and Jones\(^2\) reported on 10 baseball players treated for OCD of the capitellum by arthroscopic débridement; 4 of them were able to resume playing competitively. The average age was 14.5 years and the average follow-up was 3.9 years. However, in this study the outcomes were poorly correlated with the lesion grade.
  - Baumgarten and associates\(^1\) reported on 14 young athletes (gymnastics or throwing sports) whose OCD of the capitellum was treated by arthroscopic débridement. Three were forced to give up their sport. The average age was 13.8 years and the average follow-up was 4 years. In this review contracture was noted to improve by 14 degrees.

COMPLICATIONS

- Angular deformity
- Avascular necrosis of the capitellum
- Detachment and capitellum overgrowth
- Early arthritis

REFERENCES

DEFINITION
- Patellar instability in children and adolescents usually involves an episode of complete dislocation of the patella from the trochlear groove. Occasionally there can be episodes of patella subluxation without gross dislocation.
- There are two types of patella dislocation:
  - Acute traumatic patella dislocation
  - Atraumatic dislocations or subluxation secondary to ligamentous laxity
- First-time patella dislocations tend to occur most commonly in adolescent high-level athletes.\(^2\)
- Pain is often associated with episodes of dislocation, but chronic patellofemoral pain is not usually the primary complaint.
- The incidence of primary patella dislocation in 10- to 17-year-olds is reported at 29 and 43 per 100,000.\(^6\)

ANATOMY
- Traumatic dislocation of the patella occurs almost exclusively in the lateral direction and often results in a tear of the medial patellofemoral ligament (MPFL) off the femur or the patella or in its midsubstance (FIG 1A).
- The MPFL provides 50% to 80% of the restraining force to lateral patella displacement.\(^8\)
  - It is a flat band adjacent to the medial retinaculum that courses between the medial epicondyle of the femur and the medial patella.
  - It inserts into the superior two thirds of the patella on its medial aspect.
- Specifically, the MPFL attaches into the femur just distal to the adductor tubercle and just superoposterior to the medial epicondyle (FIG 1B).\(^12\)
- In a skeletally immature patient, the MPFL appears to attach to the femur between the growth plate and the medial epicondyle.
- Traumatic dislocation can cause a serious fracture of the medial patella facet (FIG 1C) or the lateral femoral condyle (FIG 1D) and can be cartilaginous or osteocartilaginous.
  - Stanitski found a 71% incidence of osteochondral injury at arthroscopy after patella dislocation, most of which was radiographically occult.\(^16\)
  - More frequently there is a less serious nonarticular avulsion fracture of the MPFL off the medial patella.
  - There can be an immediate or delayed appearance of an osseous lesion at the avulsion site off the medial patella (FIG 1E).
  - A shallow trochlea groove, patella alta, patellar tilt, and a lateralized tibial tubercle can increase the risk of dislocation,\(^5\) along with a hypoplastic tibial tubercle and valgus knee alignment.

PATHOGENESIS
- Noncontact patellar dislocation during sports usually involves lower extremity internal rotation combined with knee valgus on a planted foot (a mechanism very similar to anterior cruciate ligament injury).
- Less commonly, patella dislocation is caused by a direct blow that pushes the kneecap laterally.
- Most episodes of traumatic patella dislocation spontaneously reduce in the field.
- The common finding of a lateral femoral condyle bone bruise at the sulcus terminalis suggests that dislocation usually occurs at 70 to 80 degrees of flexion.\textsuperscript{14}
- Multiple anatomic factors are theorized to increase the risk of patella dislocation, such as family history, increased Q angle, femoral intorsion, tibial extorsion, knee valgus, trochlear groove dysplasia, and foot pronation. Only patella alta is a proven risk factor.\textsuperscript{3}

**NATURAL HISTORY**
- After a primary patellar dislocation, there is only a 17% risk of recurrence. The risk of recurrence jumps to 49% if there is a history of prior patellar dislocation or subluxation.
- Young age was also associated with recurrence, as was a positive family history.\textsuperscript{6}
- At 6 months after patellar dislocation, only 69% of patients had returned to sports.\textsuperscript{7}
- At 2 to 5 years of follow-up after patellar dislocation, Fithian and coworkers\textsuperscript{9} showed no radiographic or scintigraphic evidence of degenerative joint disease.
- At 6 to 26 years of follow-up after nonoperative treatment for patellar dislocation, 22% of knees showed arthritic changes compared to 11% of each patient’s opposite uninjured knee.\textsuperscript{9}
- At least 30% to 50% of patients with patella dislocation will have knee pain more than 2 years after injury;\textsuperscript{7} and 69% of athletes will decrease their sports activity.
- Young age and skeletal immaturity, especially in females, is associated with worse prognosis.\textsuperscript{11}
- Overall, the natural history is not improved with the routine operative stabilization of primary dislocations.\textsuperscript{2,4,11}

**PATIENT HISTORY AND PHYSICAL FINDINGS**
- Most episodes of patellar dislocation spontaneously reduce in the field.
- Patients with an acute traumatic patella dislocation often present to the emergency room with a history of a noncontact or contact injury to their knee, and many do not recognize the injury as a patellar dislocation.
- An effusion is usually present after traumatic dislocation but is rarely present after atraumatic dislocations. If the patella is still dislocated, the emergency physician usually performs a reduction by slowly extending the knee from its flexed position.
- Patella dislocation that spontaneously reduces in the field may mimic the history and presentation of an anterior cruciate ligament tear.
- The patella apprehension sign is the best test for patellar instability. With the knee flexed over a bolster at 25 degrees, the patella is translated laterally. If the patient exhibits apprehension, the test is positive.
- Patella glide test: With knee flexed 25 to 30 degrees, the patella is gently translated laterally. Lateral translation of more than two quadrants of the patella may indicate instability.
- Testing for the J sign (patella pulls laterally as knee reaches full extension, in the path of an upside-down J) can identify proximal alignment issues.

**DIFFERENTIAL DIAGNOSIS**
- Knee radiographs should include the anteroposterior (AP), lateral, and sunrise (or Merchant) views.
- The sunrise or Merchant view requires a patient to flex the knee 30 to 45 degrees, which may be impossible owing to pain at the initial time of presentation in the emergency department. The sunrise view can usually be obtained at the first follow-up visit.
- Plain radiographs can miss 40% of arthroscopically documented chondral or osteochondral lesions. Many reparable osteochondral injuries show only a sliver of bone on one view in the plain radiographic series, which can be easily overlooked (FIG 2A).
- Because of the high rate of occult articular or osteoarticular injury, we recommend an MRI scan on patients who present with a large traumatic effusion.
- The site of MPFL ligament disruption can often be identified on MRI. MRI is reported to be 85% sensitive and 70% accurate (FIG 2B).\textsuperscript{15}
- Patellar dislocation produces a signature bone contusion pattern in which the medial patella and the midportion of the lateral femoral condyle show increased signal (FIG 2C). This bone bruise pattern is distinct from that associated with anterior cruciate ligament tears.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**
- Anterior cruciate, medial collateral, lateral collateral, or posterior cruciate ligament tear
- Meniscal tear
- Patellofemoral pain syndrome
- Knee contusion
- Osteoarticular fracture

**NONOPERATIVE MANAGEMENT**
- Initial management of traumatic patellar dislocation after reduction is with a knee immobilizer, analgesia with oral narcotics, and crutch walking (weight bearing as tolerated).
- The risk of redislocation is three times higher in patients treated with immediate mobilization versus immobilization with cast or brace.\textsuperscript{10} The authors use a knee immobilizer for 4 weeks.
- Initial nonoperative management of acute patellar instability in children begins with the management of any residual acute symptoms, such as pain and swelling.
Small metallic or bioabsorbable screws or pins should be available for osteochondral fracture repair.

- MRI can locate the site of MPFL failure with 70% accuracy to help target the site of repair (patella versus femoral side of ligament).
- Examination under anesthesia involves testing lateral patella tracking and checking overall knee stability.

**SURGICAL MANAGEMENT**

- Operative treatment is indicated for first-time patellar dislocation that fails to reduce concentrically, or that involves osteochondral damage necessitating repair or removal of a loose body.
- Osteochondral lesions larger than 1 cm in diameter should be repaired if any bone is attached to the chondral fragment. Fixation devices should be countersunk 1 to 2 mm beneath the cartilage surface.
- The MPFL can be repaired at the time of surgery for osteochondral lesions in acute dislocations, but the recurrence rate is higher with repair versus reconstruction.
- Reconstruction (versus repair) is indicated for recurrent instability, or in patients who are noted to have an attenuated MPFL at the time of surgery.
- MPFL reconstruction is not indicated for malalignment, patellofemoral pain, or arthrosis.
- Lateral release is rarely necessary with repair or reconstruction of the MPFL.
- Recurrent traumatic dislocations and recurrent traumatic dislocations that fail bracing and physical therapy can benefit from surgical patella realignment.
- Tibial tubercle realignment procedures should be avoided in skeletally immature patients with open growth plates because of the risk of creating iatrogenic genu recurvatum from growth arrest.

**Preoperative Planning**

- MRI scans should be reviewed to determine the size and location of osteochondral fractures and their potential for repair versus removal.

- Small metallic or bioabsorbable screws or pins should be available for osteochondral fracture repair.
- MRI can locate the site of MPFL failure with 70% accuracy to help target the site of repair (patella versus femoral side of ligament).
- Examination under anesthesia involves testing lateral patella tracking and checking overall knee stability.

**Positioning**

- The patient is positioned supine on a table that will allow knee imaging (FIG 3).
- An intravenous bag is taped to the table to allow blocking the knee at about 30 to 60 degrees flexion during patella repair and reconstruction tensioning.

**Approach**

- The surgeon uses an approach through the anterior knee midline or a medial parapatellar approach. If needed, the hamstrings semitendinosus graft is harvested through a standard proximal medial tibial approach with a tendon stripper.

**Preoperative Planning**

- MRI scans should be reviewed to determine the size and location of osteochondral fractures and their potential for repair versus removal.

- Small metallic or bioabsorbable screws or pins should be available for osteochondral fracture repair.
- MRI can locate the site of MPFL failure with 70% accuracy to help target the site of repair (patella versus femoral side of ligament).
- Examination under anesthesia involves testing lateral patella tracking and checking overall knee stability.

**Positioning**

- The patient is positioned supine on a table that will allow knee imaging (FIG 3).
- An intravenous bag is taped to the table to allow blocking the knee at about 30 to 60 degrees flexion during patella repair and reconstruction tensioning.

**Approach**

- The surgeon uses an approach through the anterior knee midline or a medial parapatellar approach. If needed, the hamstrings semitendinosus graft is harvested through a standard proximal medial tibial approach with a tendon stripper.
MEDIAL PATELLOFEMORAL LIGAMENT REPAIR

- A 3- to 5-cm longitudinal incision is made centered over the medial border of the patella.
- Sharp dissection is carried to the bony surface of the patella with a subperiosteal incision down to bone in a vertical line about 1.5 cm lateral to the medial patellar border (TECH FIG 1A).
- The periosteum and all overlying soft tissues are collectively elevated off the medial 1 to 1.5 cm of the patella and a tissue plane is developed in the fatty plane between the retinaculum and synovial joint capsule using Metzenbaum or curved tenotomy scissors.
  - This soft tissue tunnel is expanded down toward the medial epicondyle of the femur.
  - It is not necessary to enter the joint space, and this should be avoided.
- A finger is placed in the tunnel that lies just outside the synovium of the knee joint but is deep to the MPFL.
- The MPFL can be digitally palpated on its inner surface down to the medial epicondyle to determine its suitability for repair versus reconstruction.
  - It should feel like a stout band of tissue originating from the medial epicondyle when traction is applied on its patellar end with a Kocher clamp (TECH FIG 1B).
- A rongeur or burr is used for superficial decortication of the exposed anterior medial patella, thus creating a bed for healing of the advanced MPFL.
- Multiple extra-articular drill holes (three or four) are placed in the patella to create transosseous suture tunnels for imbrication.
- Suture anchors can be used as an alternative for fixation to the patella (TECH FIG 1C).
- No. 2 or stronger nonabsorbable sutures are placed through the patella tunnels and woven through the advanced MPFL.
  - The MPFL should be sutured to the anteromedial surface of the patella, not the posteromedial surface (TECH FIG 1D).
  - The tension should be set with the knee at 45 to 60 degrees of flexion to prevent overcorrection or undercorrection.
- The remaining free lateral edge of the MPFL tissue is sewn down to the patellar soft tissue with a running 2-0 suture.
  - The knee should be placed through a range of motion to assess the repair’s ability to prevent dislocation and maltracking in all degrees of knee flexion and extension.
  - The wounds are irrigated and the skin is closed.

MEDIAL PATELLOFEMORAL LIGAMENT RECONSTRUCTION

- A 3- to 5-cm medial patellar longitudinal skin incision is carried down to the medial patella and the initial dissection is similar to the above MPFL repair.
- A thick periosteal flap is elevated off the medial 1 to 1.5 cm of the patella and carried down to the medial fibrofatty layer just outside the knee synovium.
- An extrasynovial tunnel is created deep to the MPFL and medial retinaculum. From inside out, the MPFL is palpated to determine its suitability for repair or the necessity for reconstruction. The MPFL should feel like a stout band originating off the medial epicondyle.
- The semitendinosus tendon (single tendon) is harvested using standard technique with a tendon stripper, and no. 2 Ethibond suture is placed in each end of tendon with a Krackow type of locking stitch (TECH FIG 2A).
  - The doubled tendon is sized usually to 5 to 6 mm in diameter.
- A 2-cm incision is made over the medial epicondyle and an anterior cruciate ligament guide pin is placed just anterior and proximal to the medial epicondyle.
  - Because the medial epicondyle is difficult to palpate, the guide pin’s location should be verified with AP and lateral fluoroscopy.
  - In skeletally immature children, the guide pin should be 4 to 5 mm distal to the growth plate.
- A 4-mm transosseous tunnel is drilled in the medial patella just superior to the equator.
- An umbilical tape is passed through the patella tunnel and under the medial retinaculum and around the guide pin to test isometry. The tape is tightened at 30 to 60 degrees of flexion.
A soft tissue interference screw matched to the tunnel size (same size) is then placed to lock the folded double end of the hamstring graft securely in the tunnel (TECH FIG 2B, C).

- If the patella tracks medially in flexion, the pin is moved distal; if the patella tracks medial in extension, the pin is moved slightly proximally. If the pin is too anterior, the tape will tighten in terminal extension and flexion. If the pin is too posterior, the tape will loosen in terminal extension and flexion.
- The Beath needle guide pin is advanced across the distal femur condyle until it comes out the lateral skin, avoiding the patellofemoral joint anteriorly and the common peroneal nerve posteriorly. A 5 × 25-mm tunnel is drilled over the guide pin.
- The tendon is folded in half and looped over a no. 5 nonabsorbable suture. The no. 5 suture ends are placed into the eyelet of the Beath needle.
- The folded end of the tendon is drawn into the tunnel as the guidewire and no. 5 suture are advanced across the knee condyles to exit laterally.

A soft tissue interference screw is placed in the femoral bone tunnel to lock the hamstring graft into the tunnel after the looped graft is pulled into the tunnel when the guide pin is advanced across the femur.

- The two free ends of the graft are routed under the medial retinaculum up toward the patella.
- One end of the tendon is passed through the patella tunnel and then sewn to the other end of the tendon with the knee flexed to about 45 degrees while the patella is held firmly in the trochlear groove.
- Patella tracking and stability are tested through a full range of motion.
- Standard closure is performed and a knee immobilizer is placed.

**GALEAZZI PROCEDURE (SEMITENDINOSUS TENODESIS)**

- The semitendinosus tendon (posterior and distal to the gracilis) is harvested with an open tendon stripper and the distal tendon is left attached to the proximal tibia.
- The free end of the tendon is secured with a Krakow type of locking stitch of no. 2 nonabsorbable suture.
- Through a midline incision, the patella is exposed to allow an oblique 4- to 5-mm drill hole placed from proximal lateral to distal medial in the coronal plane of the patella.
- A lateral release is performed about 1 cm lateral to the patella, extending from the proximal tibia to 1 cm above the proximal patella.
- The free end of the semitendinosus is passed retrograde up through the oblique tunnel and the free end is folded back across the anterior surface of the patella periosteum and sutured to the anterior patella, or sewn back to itself if its length permits (TECH FIG 3).
- The graft should be tensioned and fixed with the knee at 45 to 60 degrees flexion.
- A knee immobilizer is placed, and the patient may bear weight as tolerated. Early motion is encouraged.

**TECH FIG 2 • A.** Harvest of semitendinosus, showing the fibrous band diverging posteromedially toward the gastrocnemius. These bands must be cut before passing a tendon stripper. **B,C.** A soft tissue interference screw is placed in the femoral bone tunnel to lock the hamstring graft into the tunnel after the looped graft is pulled into the tunnel when the guide pin is advanced across the femur.

**TECH FIG 3 •** Galeazzi procedure. Semitendinosus is harvested and left attached distally. The free end of the graft is fixed into the oblique patellar tunnel.
### Pearls and Pitfalls

<table>
<thead>
<tr>
<th>Technique</th>
<th>Pitfalls</th>
</tr>
</thead>
</table>
| **MPFL repair** |  - Works best for acute traumatic dislocation in which the MPFL has avulsed off the medial patella, or off the adductor tubercle. Repair has a higher recurrence rate than reconstruction. The surgeon must test to make sure the MPFL is sturdy for repair. If it is attenuated, MPFL reconstruction should be used.  
  - Sutures should be tensioned with the knee in 30 to 60 degrees flexion and the patella well seated in the trochlear groove to avoid maltracking.  
  - The MPFL is secured to the anteromedial patella, not the posteromedial patella.  
  - The surgeon should avoid repair into a medial patella osteochondral fracture fragment; the fragment should be excised first.  
  - Suture anchors make repair much easier than multiple suture tunnels. |
| **MPFL reconstruction** |  - The isometry of the guidewire should be checked to avoid patellar maltracking before drilling the medial epicondyle tunnel.  
  - The tendon is passed through the patellar tunnel with a Hewson suture passer or a folded no. 22 steel wire.  
  - The interference screw is placed beside the doubled tendon in the epicondyle tunnel, not between the two limbs, to avoid wrapping up the tendon. |
| **Galeazzi procedure** |  - The hamstring tendon is passed retrograde through the patellar tunnel using a Huysten suture passer or a guide pin with an eyelet.  
  - The transferred hamstring tendon is tensioned with the knee flexed 30 to 60 degrees. |
| **Roux-Goldthwaite procedure** |  - The surgeon should avoid overtensioning the transferred lateral half of the patella tendon to keep adequate tension on the untransferred half. |
POSTOPERATIVE CARE

- MPFL repair and reconstruction patients are placed in a knee immobilizer and are weight bearing as tolerated. Full range of motion starts 1 to 2 weeks postoperatively, and patients are advanced to physiotherapy at 6 weeks postoperatively.
- Galeazzi procedure patients have similar rehabilitation due to solid fixation if the tendon is sewn to itself.
- Roux-Goldthwaite procedure patients are kept toe-touch weight bearing for 6 weeks postoperatively owing to the less secure fixation of the transferred tendon into medial proximal tibia soft tissue.

OUTCOMES

- MPFL reconstruction appears to be more reliable at preventing redislocation than other soft tissue procedures.
- Nomura and associates\textsuperscript{13} reported that only 2 of 22 patients had a repeat subluxation or dislocation episode after MPFL reconstruction, with an average follow-up of 11.9 years.
- Thaunat and Erasmus\textsuperscript{17} found that 3 of 148 MPFL reconstructions redislocated with an anatomically placed double loop of autogenous gracilis tendon. All failures were related to repeat trauma occurring at least 4 years from the index surgery.
- Andrish\textsuperscript{1} suggested that failed MPFL reconstructions associated with trochlear or patellar dysplasia often necessitate a trochleoplasty, tibial tubercle transfer, or both.

COMPLICATIONS

- Recurrence is seen in less than 10\% of patients after MPFL reconstruction.
- Patellofemoral pain is often unchanged from the preoperative condition.
  - Patients with severe patellofemoral arthrosis and patellofemoral pain syndrome may not benefit from these procedures.
  - Skeletally mature patients may benefit from a procedure that moves the tibial tubercle more anterior (Fulkerson osteotomy).
- Overtightening of medial soft tissue can result in medial dislocation. This is especially possible if a medial repair is tensioned in full extension or is combined with an extensive lateral release.
- Care must be taken to avoid patella articular cartilage penetration when drilling patella holes, especially with the Galeazzi procedure.
- With the Roux-Goldthwaite procedure, there are reports of patellar tendon rupture of the untransferred tendon.

REFERENCES

DEFINITION
- Instability of the patellofemoral joint is a significant cause of pain and dysfunction in children and young adults.
- Instability or dislocations may occur in either ligamentously lax individuals or in athletic non-lax individuals.
- Instability or dislocation patients without generalized ligamentous laxity are more likely to sustain an injury to the ligament and to structures about the knee.
- Injuries sustained to the medial aspect of the patellofemoral joint may lead to ligament disruption of the patellofemoral ligament with or without stretching or tearing of the medial retinaculum. This may lead to persistent pain or recurrent instability of the patellofemoral joint.
- The key to treatment is the persistent complaint of instability feelings and examination consistent with instability with or without pain.
- Care must be taken to avoid realignment surgery for pain only.

ANATOMY
- The medial restraints of the patellofemoral joint are made up predominantly of the medial retinaculum and the medial patellofemoral ligament. Forty to 60% of the resistance to lateral translation is supplied by the medial patellofemoral ligament.\(^3\)
- The medial patellofemoral ligament is about 15 mm wide. It extends from the medial aspect of the patella, about 10 to 15 mm distal to the superior pole of the patella, near the widest portion of the patella, to the medial epicondylar area just above the origin of the medial collateral ligament.
- This area can also be located distal to the vastus medialis obliquus (VMO) insertion into the quadriceps tendon and anterior to the medial intermuscular septum.
- The lateral retinaculum may also be tight, characterized by less than 12 mm of medial translation.\(^2\)
- The bony anatomy and alignment of the lower extremities must also be considered. The quadriceps angle may be greater than average, increasing the lateral translational force.
- So-called miserable malalignment syndrome may exist, including excessive femoral anteverision with or without increased external tibial torsion.\(^1,2\)

PATHOGENESIS
- The onset of patellofemoral instability or dislocation can be either traumatic or atraumatic. In young athletes, it can occur during a valgus twisting maneuver such as swinging a baseball bat while twisting out of the way of a pitch. It may also occur with a direct blow on the valgus bent knee.
- Like an anterior cruciate ligament injury, it is common to hear or feel a “pop.” If the patella completely dislocates, the athlete may be found to have a deformity of the knee and may be unable to actively extend the knee.
- It may be associated with significant swelling or little swelling. It is commonly difficult to distinguish between a medial collateral ligament tear, a meniscal tear, or an acute patellofemoral subluxation or dislocation.
- The bony anatomy of the patellofemoral joint may also be abnormal with a deficient lateral femoral slope of the trochlear groove, leading to decreased force needed to laterally translate or dislocate the patella.

NATURAL HISTORY
- Patients with an atraumatic presentation of instability or dislocation of the patellofemoral joint have a higher likelihood of repeat instability episodes despite aggressive physical therapy and bracing.\(^1,2\)
- Patients with a traumatic-onset presentation may have a fracture or loose body created by the subluxation or dislocation. If a loose body exists, as in other conditions, surgical intervention is warranted.
- There is controversy over whether to acutely operate on first-time dislocators who are young athletes without generalized ligamentous laxity.

PATIENT HISTORY AND PHYSICAL FINDINGS
- The clinician must evaluate potential associated or confounding injuries and consider the differential diagnosis, which should include (but not be limited to) meniscal tears, which are characterized by joint-line tenderness, painful popping with provocative maneuvers (full squat, McMurray, or Apley compression test), and with or without loss of full extension.
- A thorough examination will include the following:
  - Examination for effusion
  - Patellar stability testing. Instability of 25% to 50% indicates increased laxity but a still-competent retinaculum and medial patellofemoral ligament. Instability of more than 50% indicates insufficiency of both structures.
  - Femoral rotation: Average rotation is external rotation greater than or equal to internal motion.
  - Tibial alignment: Average axis is 10 to 15 degrees of external tibial torsion.
  - The clinician should observe and palpate the patella for lateral subluxation (J sign) during active range of motion.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- Anteroposterior (AP), lateral, and Merchant views are all standard and provide information regarding the acute injury. Each radiograph is evaluated for fracture or loose fragment necessitating more emergent surgical indications.

DIFFERENTIAL DIAGNOSIS
- Meniscal tear
- Medial collateral ligament tear
- Chondral injury or bruise
- Anterior cruciate ligament tear
- Tendinitis
- Sindig-Larsen-Johanssen disease

**NONOPERATIVE MANAGEMENT**
- Over 80% of patients will respond well to nonoperative treatment.
- Nonoperative treatment is appropriate for multiple dislocators or subluxators, especially those who have generalized ligamentous laxity or an atraumatic type of presentation.
- Controversy exists as to the best treatment of first-time dislocators who are ligamentously tight, with or without a traumatic (but usually forceful) event.
- First-time dislocators who are young athletes without ligamentous laxity or a loose body or fracture are the most likely to respond well to nonoperative treatment.
- Some advocate early surgical intervention to repair the medial patellofemoral ligament and medial retinaculum even without fractures or loose body.
- Nonoperative regimen for a dislocation includes:
  - Rest, ice, compression, and elevation, plus anti-inflammatory medications
  - Immobilization for about 6 weeks
  - Immediate physical therapy to strengthen the weakened quadriceps and a patellar protection program
  - Bracing, with a lateral patellar restraint type of brace, for return to activity
- Treatment options for recurrent subluxation should include:
  - Bracing with a lateral patellar restraint type of brace
  - Physical therapy: a patellar protection program emphasizing strengthening of the hip flexors, abductors (which are routinely weak in this patient population), and quadriceps in particular
  - The clinician should emphasize to the patient that therapy requires participation at home as well as at therapy sessions.

**SURGICAL MANAGEMENT**
- Operative intervention should not be considered in chronic subluxators unless they prove that despite good effort in therapy over 6 to 12 months, instability still is problematic.
- The surgeon should be wary of operative treatment for patients with pain without instability.
- Recurrent dislocators who dislocate in a brace during physical activity despite good effort during therapy and training as well as those who dislocate during activities of daily living in a brace after therapy are candidates for surgical intervention.
- Any loose body or patellar avulsion fractures with large displaced fragments are indications for early surgical intervention.

**Preoperative Planning**
- All imaging studies are reviewed for other pathology that also needs to be addressed concurrently.
- Before positioning, an examination of the knee under anesthesia (including ligamentous testing) should be performed.
- The examination should include a Lachman test, pivot shift, varus–valgus stress test, and anterior–posterior drawer as well as medial and lateral patellar stability testing at 45 degrees of knee flexion. Results should be compared with those from the opposite knee.
- Translation of the patella over 50% of the width of the patella laterally indicates an incompetency of the medial patellofemoral ligament and the medial retinaculum, and both should be addressed at surgery (**FIG 1**).

**Positioning**
- The supine position is used with the patient’s operative leg free and with a tourniquet on the proximal leg.
- The foot of the table is flexed about 30 to 45 degrees and a lateral post is used for valgus moment, visualizing the medial compartment.
- The opposite leg can be positioned per the surgeon’s preference, depending on whether the foot of the table is flexed 90 degrees or if the foot is kept flat with a lateral post.

**Approach**
- If an arthroscopic lateral release is being performed, a 4- to 5-cm limited medial approach may be used, centering on the widest portion of the patella (**FIG 2**). Subcutaneous flaps can be elevated to allow great mobility of the prepatellar skin to limit the size of the incision.
- Alternatively, an open subcutaneous lateral release can be performed through a 1-cm incision, along with the medial plication–imbrication, or both may be done through a midline incision.
MEDIAL RETINACULAR Plication (Modified Insall)

- After dissection of the subcutaneous tissues, a medial parapatellar incision is made, leaving about 2 mm of tendon with the VMO (TECH FIG 1A).
- This incision in the tendon and the retinaculum is made from about 3 to 4 cm above the superior pole of the patella distally to 3 to 4 cm distal to the inferior pole of the patella medial to the tendon, leaving enough retinaculum with the tendon to suture to.
- The entire depth of the tendon and retinaculum is incised.
- The knee is then held in 45 degrees of flexion and the patella is held in position in the center of the trochlea (TECH FIG 1B).
- Three nonabsorbable no. 1 or no. 2 sutures are placed but not tied in a horizontal mattress fashion.
- These are typically placed 25% to 40% across the width of the patella from medial to lateral, imbricating the edge of the tendon of the VMO and the retinaculum distally and laterally.
- With the three sutures held tight, the knee is placed through a range of motion, from full extension to 90 degrees of flexion, to check that enough imbrication has been performed.
- The sutures are then tied and a 0 absorbable suture is used above and below the imbrication to reinforce the tension set by these sutures.
- A running 0 absorbable suture then can be sutured over the imbrication to help reinforce the imbrication as well as lower its profile.
- The wound is irrigated and closed in layers.
- Absorbable 3-0 or 4-0 monofilament should be used in the skin.1,2

Medial Patellofemoral Ligament Reconstruction

- The incision in the quadriceps mechanism and retinaculum is kept as extrasynovial as possible, especially directly medial to the patella and distally.
- The retinaculum is dissected from the subcutaneous tissue superficially back to the medial intermuscular septum (TECH FIG 2A).
- It is then dissected from the synovium deep back to the intermuscular septum.
- A puncture hole is made in the retinaculum immediately anterior to the intermuscular septum, superficial to the medial epicondylar insertion of the natural ligament and immediately distal to the VMO.
- The distance from the widest portion of the patella to the planned puncture site is measured.
- The medial 6 to 8 mm of full-thickness quadriceps tendon is taken typically as a 50- to 60-mm-long graft remaining attached to the superior pole of the patella (TECH FIG 2B).
- The graft is subperiosteally reflected distally about 10 to 12 mm from the superior pole of the patella (more distally laterally than medially, to allow it to fold over on itself during fixation and tensioning).
- A nonabsorbable suture is placed in the free end of the graft, with a whipstitch or other graft stitch performed with two ends.
- The graft is then passed deep to the retinaculum through the puncture hole to the superficial side of the retinaculum (TECH FIG 2C).
- The tension is then set via the medial retinacular suture plication as described above before setting the tension of the graft.
- At 45 degrees of knee flexion the graft is then tensioned to allow no more than 25% lateral translation of the patella at 45 degrees of knee flexion (TECH FIG 2D).
- The graft is secured into position with no. 1 or 2 nonabsorbable suture placed through the medial intermuscular septum periosteum of the medial epicondyle and the graft and retinaculum at the puncture hole in the retinaculum.
- It is further secured by 0 absorbable sutures in the graft and retinaculum, catching the graft superficial and deep to the retinaculum as the free end of the graft is directed back toward the patella.
- The suture in the free end of the graft is also used to secure it in position.
- Once the graft is secured and imbrication is complete, the knee is flexed to 90 degrees to ensure that no overtightening of the quadriceps mechanism has occurred and that the sutures stay in place.
- Tracking of the patella is also checked as described above.4
**POSTOPERATIVE CARE**

- Patients are placed in a hinged postoperative knee brace locked in full extension.
- Physical therapy for range of motion (passive and active assisted) should be started in the first few days to combat arthrofibrosis.
- Weight bearing is protected with crutches until the patient is comfortable enough to walk in a locked knee brace in full extension.

- During the initial phase of therapy, patellar mobilization, quadriceps activation, straight-leg raises, pain modalities, and edema control are important.
- Range of motion is restricted to 0 to 90 degrees for the first 3 to 4 weeks postoperatively.
- At 4 weeks, full range of motion is allowed, with progressive quadriceps strengthening, edema control, and pain control, and gait training is initiated.
- Brace use in community settings is continued until adequate quadriceps strength has returned (about 6 weeks).

**PEARLS AND PITFALLS**

**Indications**
- Careful patient selection process is a must.
- Patients with pain without instability should not be operated on unless all else fails.
- A careful examination should be done to determine whether reconstruction of the medial patellofemoral ligament is warranted.

**Tension setting**
- The surgeon should make sure that the patella translates close to 25% of its width laterally.
- The patella should also medially translate 12 to 20 mm.
- This is best done by setting the tension with the knee flexed about 45 degrees.
- If medial patellofemoral ligament reconstruction is being performed at the same time, the tension should be set with the retinacular imbrication before tensioning the graft (this avoids over-tensioning).
- Before closure, the knee is taken through the range of motion from 0 to 90 degrees to ensure good alignment and to make sure that the sutures are not under too much tension.

**Quadriceps graft management**
- Care must be taken not to detach the quadriceps graft from the patella completely.
- Dissecting more distally on the lateral aspect of the patellar attachment allows for the graft to lay down on itself.
- The puncture site is positioned distal to the most inferior aspect of the VMO and immediately anterior to the intermuscular septum.
- When passing the graft through the puncture hole in the retinaculum, a snap or Kocher clamp is used to hold the stitch in the free end. It is pulled through in line with the graft (the surgeon should push anterior to posterior, not pull posterior to anterior).

**Fixation problems**
- The graft is sutured at the patellar attachment as it folds over itself.
From 6 to 12 weeks, there is continued progression of quadriceps strengthening.
Functional return to activities starts at 3 months postoperatively.

COMPlications
- Failure of fixation is typically seen at the time of surgery if knee is tested from 0 to 90 degrees.
- Late fixation failure is uncommon but can happen if flexion beyond 90 degrees is started too soon postoperatively.
- Arthrofibrosis should be treated aggressively with manipulation under anesthesia if greater than 90 degrees of flexion is not obtained by 6 weeks.
- Continued pain may occur, especially if not enough or too aggressive of a lateral release was performed, leading to either increased pressure on the patella or medial pressure and instability.
- Injury to the cutaneous nerves is common, and patients should be warned of this risk. It can be avoided with well-placed small incisions.
- Recurrent instability may occur in patients with rotational or angular malalignments that either are not recognized or cannot be addressed because of skeletal immaturity.

REFERENCES
DEFINITION
- Tibial spine fractures are synonymous with an avulsion of the anterior cruciate ligament (ACL) with its attachment on the anteromedial portion of the tibial eminence.\(^{16,21}\) Some authors consider them to be equivalent to the midsubstance ACL injuries seen in the adult population.
- This injury commonly occurs in the younger age group, particularly in those with open growth plates.
- Tibial spine fractures occur in 3 per 100,000 children each year.\(^{18}\)
- Meyers and McKeever classified this fracture into three types based on the degree of displacement (FIG 1)\(^{14}\):
  - Type I is a nondisplaced fracture.
  - Type II is the hinged, partially displaced type.
  - Type III is a complete displacement of the fragment.
- The classification proposed by Meyers and McKeever was later modified by Zaricznyj to include a fourth type, which would signify a comminuted fragment.\(^{22}\)

ANATOMY
- The tibial eminence is found lying in the intercondylar area of the tibia (FIG 2).
- Two elevations are seen: a medial and a lateral. These elevations are triangular.
  - The medial elevation provides the attachment for the fibers of the ACL.
  - There are no structures that attach to the lateral portion of the eminence.
  - The ligamentous ends of the medial and lateral menisci likewise insert into the intercondylar eminence.
  - The tibial eminence also serves as an insertion for the posterior cruciate ligament (PCL); the fibers of the PCL typically arise from the posterior portion of the intercondylar eminence.\(^{14}\)
- In the younger child the majority of the anterior portion of the eminence is cartilaginous.\(^{14}\)

PATHOGENESIS
- Avulsion of the tibial eminence or tibial spine is usually traumatic in nature. It is more common in children, particularly those with incomplete ossification and open growth plates. The incompletely ossified tibial spine is primarily cartilaginous, which is weaker in resisting tensile forces.
- The injury occurs because of a stretching of the ACL. The ACL is much stronger in resisting tensile forces than the immature osteochondral surface; this often results in failure and avulsion of the osteochondral attachment of the ACL.
- The usual mechanism of injury is a forced valgus moment applied to the knee, which is coupled with external rotation forces. Other mechanisms reported include hyperextension of the knee coupled with rotational moments.
- Different loading mechanisms are likewise implicated in the development of the injury. Experimental models have shown that rapid loading rates result in midsubstance ACL tears, whereas gradual loading results in tibial spine avulsion fractures.\(^{16,21}\)
- The inherent anatomy of the knee has likewise been implicated. Kocher and colleagues\(^{10}\) compared 25 skeletally immature knees with tibial spine fractures against 25 age-matched skeletally immature knees with midsubstance ACL tears and found a narrower notch width (intercondylar notch) in individuals who had sustained the midsubstance ACL tears.

PATIENT HISTORY AND PHYSICAL FINDINGS
- Fractures of the tibial spine are usually precipitated by an acute traumatic event. The clinical presentation usually coincides with the severity of injury.
- Usually a patient with a tibial spine injury will have a history of trauma or sports-related injury; the most common mechanism is usually a fall from a bicycle. Lately, sports-related injuries have been reported with increasing frequency. High-velocity trauma may also cause tibial spine injuries.
- The patient will usually present with a painful swollen knee. Swelling is secondary to hemarthrosis from the intra-articular knee injury.
- Knee joint laxity is present, as well as an inability to bear weight on the affected extremity.
- The knee should also be carefully examined for any concomitant injury.
- Gentle palpation and examination of the knee are undertaken. Most patients have some degree of swelling due to hemarthrosis secondary to the intra-articular fracture. Other superficial injuries are related to the degree and nature of the traumatic event.
In the presence of a deficient ACL complex, during the pivot shift test the femur falls posteriorly in relation to the tibia as the leg is raised and rotated internally. The valgus force applied to the leg along with slight flexion of the knee results in the pivot shift phenomenon. The intact iliotibial band reduces the femur when the knee is brought into 20 to 30 degrees of flexion.

A positive anterior drawer test indicates knee joint laxity. However, this is not as sensitive as the Lachman test in assessing for ACL deficiency.

A positive result on the Lachman test indicates deficiency of the ACL complex. The test has greater sensitivity and specificity for ACL tears.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Standard anteroposterior (AP) and lateral views of the knee are usually adequate in making the diagnosis. These views help to define and identify the extent of bony injury.
  - In lesions that are predominantly cartilaginous, these views may sometimes detect a small piece or a fleck of avulsed bone, which may be indicative of the avulsed osteochondral fragment (FIG 3).
  - MRI is a good imaging modality for suspected tibial spine injuries, especially in the immature knee, where the tibial spine is predominantly cartilaginous. It differentiates between a true midsubstance ACL injury and a true avulsion fracture of the tibial spine. It also helps to detect concomitant injuries around the knee joint.8
  - Computed tomography is helpful in the older age group and in cases of severe trauma, where the fracture configuration may be severely comminuted.

**DIFFERENTIAL DIAGNOSIS**

- ACL tear
- Osteochondral lesion
- Meniscal injury
- Other ligamentous injuries about the knee

**NONOPERATIVE MANAGEMENT**

- Nonoperative management is reserved for nondisplaced type I fractures and reducible type II fractures.
- Type II fractures may be reduced by first aspirating the hematoma and injecting a local anesthetic agent into the joint space.
  - The knee is extended in an attempt to reduce the fracture fragment. The mechanism is through direct pressure exerted by the lateral femoral condyle.
  - This maneuver may be effective for lesions that are large enough to include part of the tibial plateau.
  - In small lesions, the maneuver may not afford adequate reduction.
  - The reduction is assessed with radiographs and the knee is immobilized.
  - A long-leg cast is placed to immobilize the leg and maintain reduction.
  - There has been controversy about the optimal position for cast placement.
  - We recommend long-leg casting between 10 and 20 degrees of knee flexion.
  - The reduction should be checked after 1 week and at 2 weeks. Any loss of reduction warrants an operative reduction of the fracture.

**SURGICAL MANAGEMENT**

- The general indications for surgical management of tibial spine fractures include:
  - Completely displaced tibial spine fractures (type III)
  - Type II tibial spine fractures with inadequate closed reduction

**Preoperative Planning**

- Careful preoperative evaluation and preparation are always imperative to the success of treatment.
- All imaging studies obtained before surgery should be reviewed.
If the avulsed fragment has a relatively large osseous component, plain radiographs will usually suffice in determining treatment. In lesions that are primarily cartilaginous, MRI may be required to determine the extent of the lesion. Any other lesion noted on imaging studies should likewise be addressed. A thorough physical examination should be performed under anesthesia. The choice of surgical treatment (open versus arthroscopic reduction) as well as the choice of fixation device largely depends on the preference and experience of the surgeon and the character of the lesion. Larger lesions with an adequate osseous component, for example, may allow for screw fixation, whereas a lesion that is primarily cartilaginous may be better treated with suture fixation. Inevitably, the final decision as to which fixation device is best is made intraoperatively.

The surgeon should be prepared to offer fixation techniques that will provide stable anatomic fixation by open methods or through arthroscopy.

Positioning
- For arthroscopic procedures, the position largely depends on the surgeon’s preference. A variety of positions can be used. The leg can be placed on the operating table with the knee joint past the break in the table. This allows the knee to flex 90 degrees when the lower end of the table is dropped down, allowing the knee to dangle off the table. This position can be done with or without a leg holder (FIG 4A).
- The leg can be placed supine on the operating table, with the hip flexed and the knee flexed 90 degrees. The knee is allowed to angle off the table as needed (FIG 4B, C).
- For open reduction techniques, the patient is placed supine on the operating table, a tourniquet is placed on the thigh, and the knee is draped in a standard fashion. The leg is exsanguinated.

Approach
- The standard arthroscopic portals used for ACL reconstruction are used (FIG 5).
- For open reduction and internal fixation (ORIF), the knee is approached through a limited parapatellar approach.

**FIG 4 • Position of the knee in the leg holder.**

**FIG 5 • The standard portals used for anterior cruciate ligament reconstruction are the same ones commonly used for arthroscopic treatment of tibial spine fractures.**

**ARTHROSCOPY-ASSISTED Tibial Spine Repair**

**Arthroscopic Fixation**
- An anterolateral portal is made for visualization, a superomedial portal is used as an outflow tract, and an anteromedial portal is made for instrumentation.
- The hemarthrosis is removed to allow for direct inspection and evaluation of the knee joint.
- Any concomitant injuries are identified.
- The base of the fracture fragment is débrided using shavers and curettes and the fracture hematoma is carefully removed.
- A posterior force is applied to the leg and an attempt is made to reduce the fracture fragments (TECH FIG 1).
If any interposing structure is found preventing reduction, it should be carefully retracted and sutured or repaired if necessary.

Midpatellar tendon portals may be added to allow the use of accessory probes and instruments.

**Screw Fixation**

- Once anatomic reduction of the fracture has been achieved, a guide pin is passed through the fracture fragment (TECH FIG 2A,B).
  - The position of the guide pin is checked under fluoroscopy to ensure proper placement and to avoid traversing the growth plate.
  - A second pin may be introduced, depending on the stability of the fracture reduction, to maintain the fragments in place.
  - A screw of appropriate size and length is chosen.
    - A 3.5-mm or 4.0-mm cannulated, self-drilling self-tapping screw is used. The screw size is largely dependent on whether the fracture fragments will accommodate the screw.
    - One or two screws may be placed, depending on the size of the fragment.

- With reduction maintained, the screw is gradually advanced under fluoroscopic guidance, making sure that the growth plate is not traversed.
- Once adequate fixation has been obtained, the guide pins are removed.
- The knee is gently flexed and extended while the stability of the reduction is checked under direct vision.
- AP and lateral radiographs of the knee are taken to document appropriate positioning of the screw and to document the fixation before closure (TECH FIG 2C–E).
- Once satisfactory reduction is documented, the instruments are removed and the arthroscopic portals closed.
- The knee is placed in a cylinder cast in 5 to 10 degrees of flexion.

**Suture Fixation**

- Two 1-0 PDS sutures are placed at the base of the ACL proximal to its insertion on the tibial spine (TECH FIG 3).
- An incision is made 1 to 2 cm medial to the tibial tubercle to allow for placement of the ACL tibial guide.
- Two parallel 2-mm transphyseal tunnels are made.
- A suture passer is passed through each tunnel and the suture ends are retrieved.

---

**TECH FIG 2** • Arthroscopic screw fixation.

A. The fracture fragment is maintained using cannulated guidewires. B,C. A cannulated screw is inserted under fluoroscopic guidance. D,E. AP and lateral radiographs showing the tibial spine fracture fixed with a single cannulated screw with washer. Care should be taken to avoid crossing the physis with the screw.

**TECH FIG 3** • Suture fixation. Two 1-0 PDS sutures are passed through the base of the anterior cruciate ligament. A suture passer is used to grab the suture ends through a transphyseal tunnel and the suture ends are tied in the anteromedial border of the tibia.
The tibial spine is reduced in its own bed and the suture ends are tied over a bone bridge in the anteromedial portion of the tibia.

The reduction is checked under direct visualization. If reduction is found to be inadequate, fixation may be augmented with percutaneous Kirschner wires or cannulated screws as needed.

Once adequate reduction had been achieved, gentle flexion and extension of the knee is performed to check for stability of reduction.

When satisfactory reduction of the fracture is obtained and documented, then the instruments are removed and the arthroscopic portals are closed.

The knee is placed in a cylinder cast in 5 to 10 degrees of flexion.

**Kirschner Wire Fixation and Percutaneous Pinning**

After adequate reduction of the fracture is obtained, the fracture fragment is held in reduction.

Two Kirschner wires are inserted percutaneously under fluoroscopic guidance 0.5 cm proximal to the tibial tuberosity on the medial and lateral side of the patellar tendon.

The Kirschner wires are withdrawn gradually in a retrograde manner until the tips are flush with the surface of the tibial spine (TECH FIG 4A).

Proper placement of the Kirschner wires is documented radiographically and arthroscopically.

The stability of reduction is checked with gentle passive flexion and extension of the knee.

The Kirschner wires are bent and cut at the level of the skin.

The instrumentation is removed and the arthroscopic portals are closed.

Adequate padding is applied over and beneath the pins to allow for support before cast immobilization.

A cylinder cast is applied to the knee in 5 to 10 degrees of flexion (TECH FIG 4B, C).

**OPEN REDUCTION AND INTERNAL FIXATION**

**Exposure**

The procedure begins with a standard median parapatellar approach. The skin incision may be parapatellar or midline.

The median parapatellar incision is started at the inferior pole of the patella and follows the medial border of the infrapatellar tendon down to the level of the tibial tubercle. The incision can be extended as needed (TECH FIG 5).

When performing the medial parapatellar skin incision, care should be taken to avoid inadvertent transection of the infrapatellar branch of the saphenous nerve; if a branch is cut it should be buried in fat to decrease the risk of developing a neuroma.

The skin incision is carried down to the fascia. The skin and subcutaneous tissues are retracted and reflected.

![TECH FIG 5 • A. Median parapatellar approach to the knee can be done through a straight midline incision. B. The parapatellar incision is carried through to the knee joint and the patella is reflected laterally.](image-url)
Dissection is carried through the medial border of the patellar retinaculum, making sure to retain at least a 2- to 3-mm cuff of soft tissue to allow for adequate closure, and down along the medial border of the patellar tendon. The patella and patellar tendon are retracted laterally to allow for direct visualization of the ACL and tibial spine fracture.

**Fracture Fixation**

- Once complete exposure of the knee joint is achieved, the fracture fragments as well as any concomitant injuries are identified.
- The leg is held in the posterior drawer position by the assistant to allow for an easier reduction.

Fixation materials used to hold the fragment in place, including sutures, screws, and Kirschner wires, are similar to those described in the arthroscopic technique.
- Once fixation of the fracture has been achieved, stability is tested by gentle flexion and extension of the knee.
- Any concomitant injuries about the knee joint are addressed.
- Copious washing of the knee joint is done before closure to clear the knee joint of any remaining debris.
- Meticulous hemostasis and layer-by-layer closure are performed.
- The knee is placed in a cylinder cast in 5 to 10 degrees of flexion.

### PEARLS AND PITFALLS

#### Indications
- A careful assessment of the injury is done before treatment; any concomitant injuries such as meniscal tears or injuries to the collateral ligaments should be carefully evaluated and incorporated into the surgical plan.

#### Surgical preparation
- Even with proper preoperative planning, the surgeon should be prepared to use a variety of fixation devices and techniques. This is often dictated by the size and character of the fracture fragment. A large fragment may accommodate more than one screw; a smaller fragment, however, may be better treated with suture fixation or percutaneous pinning.

#### Fracture fixation
- The fracture fragment should be assessed and carefully fixed. Multiple attempts at obtaining purchase with the use of fixation devices should be avoided as this may cause comminution of the fragment.
- In skeletally immature individuals, care must be taken to avoid crossing the physis, particularly with the use of screw fixation. Fluoroscopic guidance should be used and the physis identified and avoided during fixation.

#### Fracture reduction
- Difficult reduction is often secondary to soft tissue interposition. The fracture bed should be cleared and any interposing soft tissue should be retracted or removed as deemed necessary. Often the anterior horn of the medial meniscus becomes entrapped; performing an anterior drawer maneuver may allow the entrapped fragment to be liberated. The fragment may then be reduced onto the fracture bed and fixed accordingly.

#### Mobilization
- Early mobilization should be undertaken to avoid postoperative stiffness. Mobilization is allowed depending on the stability of fixation. If prolonged immobilization is needed, immobilizing in extension is preferred, as flexion contractures are a more difficult problem to treat.

### POSTOPERATIVE CARE

- Postoperatively the knee is immobilized in 5 to 10 degrees of flexion. If adequate fixation is obtained, then the extremity may be placed in full extension; hyperextension should always be avoided.
- Radiographs are taken to document adequate reduction of the fracture fragment.
- Early range of motion may be started at 1 to 2 weeks when the swelling has subsided and if good fixation of the fracture fragment is obtained.
- In more severe cases, where stability may be in question, range-of-motion exercises are generally instituted once adequate healing of the fracture can be ascertained; this is usually 4 to 6 weeks after surgery.

### OUTCOMES

- Residual laxity of the knee is commonly seen, even with anatomic reduction of the fracture, and is due to the inherent stretch of the ACL before the tibial spine fails. Excellent functional outcomes have been reported despite the residual laxity with both closed management and operative treatment of tibial spine fractures, as long as reduction is maintained.\(^2,11,19,20\)
- Good to excellent outcomes have been reported with ORIF as well as arthroscopic reduction with suture fixation,\(^1,5,11\) arthroscopic reduction with screw fixation,\(^9,17\) and arthroscopic reduction and percutaneous pin fixation.\(^13\)
- Hunter and Willis’ found similar outcomes with both screw and suture fixation. In 10 cases they found interposition of the intermeniscal ligament that required retraction or resection to allow for adequate reduction.

### COMPLICATIONS

- Nonunion
- Malunion
- Arthrofibrosis\(^4\)
- Residual laxity
- Implant-related complications
- Growth disturbance
- Loss of motion

Chapter 23

Anterior Cruciate Ligament Reconstruction in the Skeletally Immature Patient

J. Todd R. Lawrence and Mininder S. Kocher

DEFINITION

- Skeletally immature patients have open growth plates, or physes, and thus have growth potential remaining.
- Intrasubstance anterior cruciate ligament (ACL) injuries were once considered rare in this population, with tibial eminence avulsion fractures considered the pediatric ACL injury equivalent. However, intrasubstance ACL injuries in children and adolescents are being seen with increasing frequency and result in an “ACL-deficient knee” as in adult patients.
- ACL deficiency in the skeletally immature patient usually results in an unstable knee at risk for further injury and accelerated degeneration.
- Conventional surgical reconstruction techniques risk potential iatrogenic growth disturbance due to physeal violation, and thus special consideration must be given to this patient population.
- The physiologic age of the patient reflects the amount of remaining growth potential and heavily influences the treatment options.

ANATOMY

- The ACL originates from a semicircular area on the posterior portion of the medial aspect of the lateral femoral condyle and courses obliquely to the anteromedial aspect of the tibial plateau at the anterior tibial eminence (or spine).
- The primary role of the ACL is to resist anterior translation and rotation of the tibia on the femur.
- The ligament is composed of two anatomically and biomechanically distinct bundles, the anteromedial and the posterolateral bundles.
  - The anteromedial bundle is more anterior and vertical in orientation. It largely resists anterior translation and tightens in the last 30 degrees of extension.
  - The posterolateral bundle is more posterior and oblique in orientation. It is more isometric and plays a greater role in rotational control.
- Not all skeletally immature patients are the same. Some have a tremendous amount of growth remaining, while others are essentially done growing.
- Most of the longitudinal growth of the lower extremities comes from the distal femur and the proximal tibia. The tibial physes can be as close as 15 to 20 mm to the tibial spine. The femoral physes comes within millimeters of the femoral attachment of the ACL at the most posterior aspect of its insertion (FIG 1).

PATHOGENESIS

- The etiology of ACL injury in skeletally immature patients is similar to that in the adult population. It is usually due to a noncontact injury involving a cutting, pivoting, or rapid deceleration maneuver.
- Patients often report hearing a “pop” followed by swelling of the knee. ACL injury has been reported in up to 65% of pediatric patients with acute traumatic hemarthroses.
- The “shift” that occurs with the ACL-deficient knee at the time of injury causes an impaction injury on the posterior aspect of the tibial plateau against the distal femur at the sulcus terminalis as the tibia translates anteriorly on the femur. Characteristic bone bruises in this location on MRI are pathognomonic for ACL injury (FIG 2).
- Ligamentous, meniscal, and chondral injuries are commonly associated with ACL injury.
  - The medial collateral ligament is commonly injured with the ACL.
  - The posterolateral corner is less often injured with the ACL but is a common cause of failure of ACL reconstruction if it is not addressed as well.
  - Tears of the lateral meniscus are associated with acute tears of the ACL.
  - The posterior horn of the medial meniscus is a secondary restraint to anterior translation of the tibia. In the chronically ACL-deficient knee the posterior horn of the medial meniscus assumes a greater role in preventing anterior translation and is thus at increased risk of injury.

NATURAL HISTORY

- Partial tears may be successfully managed nonoperatively in some patients.

FIG 1 • Sagittal MRI demonstrating the relationship of the anterior cruciate ligament to the distal femoral and proximal tibial physes. (From Kocher MS, Garg S, Micheli LJ. Physeal sparing reconstruction of the anterior cruciate ligament in skeletally immature prepubescent children and adolescents: surgical technique. J Bone Joint Surg Am 2006;88A[Suppl 1 Pt 2]:283–293.)
PATIENT HISTORY AND PHYSICAL FINDINGS

Adolescents are notoriously bad historians, but every attempt should be made to garner an appreciation for the mechanism of injury, a history of acute or recurrent effusions, and a sense of instability with activities or mechanical symptoms.

Physiologic age should be established informally in the office using the Tanner staging system. This can be confirmed in the operating room after the induction of anesthesia. Skeletal age can be determined via hand and wrist radiographs or the method of Greulich and Pyle.

A complete examination of the knee should be performed. Particular attention should be given to evaluating the knee for associated pathology.

Patella ballotttement and fluid wave test should be done to evaluate for the presence of an effusion.

Range of motion (ROM) is important to assess because regaining full ROM before ACL reconstruction may be critical to prevent postoperative arthrofibrosis. Loss of extension should alert the clinician to the possibility of a displaced bucket-handle tear or preoperative arthrofibrosis. Loss of flexion may be due to pain secondary to a tense effusion.

Tenderness to palpation should be assessed and localized specifically as it can greatly direct the diagnosis of related injuries.

Tenderness to palpation along the joint line, particularly the posterior aspect of the joint line, should alert the clinician to the possibility of a meniscal tear. Pain or palpable popping with provocative maneuvers, such as McMurray, Apley compression, or duck walk, will help to confirm this finding.

Pain along the course of or at the femoral or tibial insertion points for the collateral ligaments should alert the clinician to the possibility of a collateral ligament tear.

Pain at the physis should prompt an investigation for a physeal injury, although in our experience this is not commonly associated with complete ACL injuries.

Tenderness along the medial retinaculum or the course of the medial patellofemoral ligament can indicate an acute patellar dislocation that reduced spontaneously.

Ligamentous evaluation should include the anterior and posterior cruciate ligaments, the medial and lateral collateral ligaments, and the posterolateral corner.

Skeletally immature athletes have a greater degree of physiologic laxity than adult athletes, and as such a comparison should always be made to the uninjured knee.

Evaluation of the ACL is best done with the Lachman test in the cooperative patient. In the patient who voluntarily or involuntarily guards against traditional Lachman testing, the prone Lachman may encourage relaxation and give a more reliable examination.

Pivot shift testing may be performed in the office but is usually not well tolerated by pediatric patients. It should be performed in the operating room as part of the preoperative evaluation of every patient.

The posterior cruciate ligament should be evaluated using the posterior drawer test. The relative starting point should always be assessed first and compared to the contralateral side. The utility of posterior drawer stress radiographs is unclear at this time. Injuries of grade II and above should alert the clinician to the possibility of an associated posterolateral corner injury.

Medial and lateral collateral ligament injuries are assessed through stress opening with valgus and varus stress at 0 and 30 degrees of knee flexion. In the pediatric patient, opening with varus and valgus stress can be due to physeal injuries, and the clinician should always be vigilant for this.

Evaluation of the posterolateral corner is best done with the dial test. The posterolateral drawer and the external rotation recurvatum tests are also useful for evaluating posterolateral corner injuries.

Evaluation for patellar instability with apprehension testing should be performed.

Evaluation of quadriceps bulk and strength is important for postoperative recovery.

IMAGING AND OTHER DIAGNOSTIC STUDIES

All pediatric patients with a complaint of knee pain should receive an initial plain radiographic evaluation including AP, lateral, and patellar views. Special attention should be given to evaluate for physeal injuries as well as other injuries on the differential diagnosis.

AP and frog-lateral plain radiographs of the hip should be considered in the evaluation of all pediatric patients with complaints of knee pain.

Overall varus and valgus malalignment, if present clinically, should be evaluated with full-length, hip-to-ankle radiographs.
MRI is the diagnostic imaging test of choice for further evaluation of ACL tears in the skeletally immature patient. However, it is significantly less sensitive and specific for diagnosing ACL injuries in this population compared with the adult population. Findings on MRI signifying an ACL tear include a discontinuity in the fibers on the ACL and a characteristic bone bruise pattern on the distal femur and the posterior tibial plateau of the lateral hemi-joint.

MRI in the pediatric population also has a high false-positive rate for meniscal tears. This is likely due to the increased vascularity of the meniscus, which is often interpreted as intrasubstance degeneration or a tear of the meniscus.

Differential Diagnosis

- Tibial eminence (spine) fracture
- Other intra-articular or physeal fracture
- Patellar dislocation
- Meniscal tear
- Posterior cruciate ligament tear
- Medial or lateral collateral tear
- Posterolateral corner injury
- Physiologic laxity
- Hip etiology

Nonoperative Management

- Partial or incomplete tears can be successfully managed nonoperatively in some patients if clinical and functional stability is possible. The following criteria have been shown to be associated with successful nonoperative treatment of partial tears:
  - Tears of less than 50% of the ligament
  - Relative preservation of the posterolateral bundle
  - Age less than 14 years
  - Normal or near-normal Lachman or pivot shift test
- Up to a third of patients may require subsequent reconstruction and should be made aware of that risk at the onset of treatment.
- Successful treatment based on the above criteria includes:
  - A hinged knee brace is worn for 12 weeks.
  - Touch-down weight bearing is maintained for 6 to 8 weeks.
  - Passive terminal extension is restricted for the first 6 weeks.
  - Active terminal extension is restricted for 12 weeks.
  - Physical therapy emphasizes hamstring muscle strengthening.
- Return to sports and active play is permitted at 3 months with the use of a functional knee brace for 2 years for cutting and pivoting activities.
- Nonoperative management of complete tears in skeletally immature patients generally has a poor prognosis.
- For prepubescent patients with a complete ACL tear and without concurrent chondral injury requiring stabilization or meniscal injury requiring repair, we favor attempted nonoperative treatment with activity modification, functional bracing, and continued rehabilitation.
- In our experience, compliance with activity modification and brace use and effectiveness limits the success of this treatment.
- Delay in surgical stabilization can lead to further meniscal and chondral injury due to recurrent instability.
- Although results of nonoperative management are generally poor, the risk of further intra-articular injury by waiting until skeletal maturity to undergo reconstruction must be weighed against the risk of growth disturbance with early reconstruction.
- Some patients are able to cope with their ACL insufficiency or modify their activities, allowing for further growth and aging such that an adolescent-type reconstruction can be performed with transphyseal hamstrings tendons in a more anatomic manner.
- For prepubescent patients with recurrent instability despite the above treatment, reconstruction is indicated.
- For adolescent patients with growth remaining who have a complete ACL tear, we do not advocate initial nonoperative treatment since the risk of functional instability with injury to the meniscal and articular cartilage is high, the risk and consequences of growth disturbance from ACL reconstruction are less, and the transphyseal technique is an anatomic reconstruction.

Surgical Management

- Conventional adult ACL reconstruction techniques risk potential iatrogenic growth disturbance due to physeal violation, and cases of growth disturbance have been reported in animal models and clinical series.
- The following principles should be applied when considering any reconstructive strategy:
  - Hard fixation, such as with an interference screw, or any bone crossing the physe, has a high risk of inducing a growth disturbance.
  - A tensioned soft tissue graft in a bone tunnel across the physe can also induce a growth disturbance.
- The approach to ACL reconstruction in the skeletally immature patient should be based on physiologic age.
- A variety of reconstructive techniques have been used, including physeal-sparing, partial transphyseal and transphyseal methods using various grafts.
- In prepubescent patients with large amounts of growth potential remaining, we perform a physeal-sparing, combined intra-articular and extra-articular reconstruction using autogenous iliotibial band.
- Recognizing that the physeal-sparing reconstruction described here is nonanatomic, we counsel patients and families that revision reconstruction may be needed if recurrent instability develops, but that this procedure may temporize for further growth such that the patient may then undergo a more conventional reconstruction with drill holes.
- A variety of other physeal-sparing reconstructions have been described to avoid tunnels across either the distal femoral or proximal tibial physe, but they will not be described here.
- In adolescent patients with significant growth remaining, we perform transphyseal ACL reconstruction with autogenous hamstring tendons with fixation away from the physe.
- In adolescent patients approaching skeletal maturity, we perform conventional adult ACL reconstruction with interference screw fixation using either autogenous central-third patellar tendon or autogenous hamstrings (see Chap. SM-10).
- In skeletally immature patients, as in adult patients, acute ACL reconstruction is not performed within the first 3 weeks after injury to minimize the risk of arthrofibrosis.
- Prereconstructive rehabilitation is performed to regain ROM, decrease swelling, and resolve the reflex inhibition of the quadriceps.
Skeletally immature patients must be emotionally mature enough to actively participate in the extensive rehabilitation required after ACL reconstruction.

Preoperative Planning
- All imaging studies, including plain radiographs and MRI, should be reviewed and associated injuries identified.
- In general, associated injuries, such as meniscal, articular cartilage, or other multiple ligament injuries, should be addressed at the time of ACL reconstruction. However, reconstruction may be staged in some cases, such as nonoperative treatment of a medial collateral ligament injury before ACL reconstruction.
- Consideration should be given to using pediatric anesthesia services, given the age of the patient.
- Tanner staging should be confirmed at the time of surgery after the induction of general anesthesia.
- A complete ligamentous knee examination, including Lachman, pivot shift, varus and valgus stress, posterior drawer, and dial tests, should be performed and the findings compared to the contralateral side to confirm the diagnosis.

Positioning
- For both procedures described here, the physeal-sparing combined intra-articular and extra-articular reconstruction with autogenous iliotibial band and the transphyseal reconstruction with autogenous hamstrings with metaphyseal fixation, positioning and setup are very similar.
- The procedure is performed under general anesthesia with overnight observation. Regional anesthesia can assist with pain relief but is not required. Local anesthesia with sedation may not be reliable in this population and has the potential for a paradoxical effect of sedation.
- The patient is placed supine on the operating room table and moved close to the operative side of the table such that the operative leg easily drapes over the edge of the table.
- A tourniquet is placed high about the upper thigh. It is routinely used during the physeal-sparing procedure but is not routinely used during the transphyseal technique.
- A side post is placed two fingerbreadths above the flexed knee as it drapes over the side of the bed. It is used in the “up” position for the diagnostic arthroscopy and dropped to the “down” position to provide a ledge for supporting the knee during the ACL reconstruction.

Approach
- The approach depends on the technique employed and the choice of graft.
- Autograft is preferred, but soft tissue allograft could be considered based on patient preference. Allograft would negate the need for hamstring harvest in the transphyseal reconstruction.
PHYSEAL-SPARING, COMBINED INTRA-ARTICULAR AND EXTRARTICULAR RECONSTRUCTION WITH AUTOGENOUS ILIOTIBIAL BAND IN PREPUBESCENT PATIENTS

Harvest of Iliotibial Band Graft
- An incision of about 6 cm is made obliquely from the lateral joint line to the superior border of the iliotibial band.
- Proximally, the iliotibial band is separated from subcutaneous tissue using a periosteal elevator under the skin of the lateral thigh.
- The anterior and posterior borders of the iliotibial band are incised and the incisions carried proximally under the skin using curved meniscotomes (TECH FIG 1A).
- The iliotibial band is detached proximally under the skin using a curved meniscotome or an open tendon stripper. Alternatively, a counter-incision can be made at the upper thigh to release the tendon.
- Dissection is performed distally to separate the iliotibial band from the joint capsule and from the lateral patellar retinaculum (TECH FIG 1B).
- The iliotibial band is left attached distally at the tubercle of Gerdy (TECH FIG 1C).
- The free proximal end of the iliotibial band is tubularized with a no. 5 Ethibond whipstitch and wrapped in a moist sponge until needed later.

Arthroscopy
- Diagnostic arthroscopy of the knee is performed through standard anterolateral viewing and anteromedial working portals.
- Management of meniscal injury or chondral injury is performed if present.
- The ACL remnant is excised with the use of biting instruments and the shaver.
- The over-the-top position on the femur and the over-the-front position under the intermeniscal ligament are identified and cleared of excess tissue to allow passage of the graft.
- Minimal notchplasty is performed to avoid iatrogenic injury to the perichondrial ring of the distal femoral physis, which is very close to the over-the-top position.2

Graft Passage
- The free end of the iliotibial band graft is brought through the over-the-top position using a full-length clamp (TECH FIG 2A) or a two-incision rear-entry guide (TECH FIG 2B) and out the anteromedial portal (TECH FIG 2C,D).
- A second incision of about 4.5 cm is made over the proximal medial tibia in the region of the pes anserinus insertion.
- Dissection is carried through the subcutaneous tissue to the periosteum.
- A curved clamp is placed from this incision into the joint under the intermeniscal ligament (TECH FIG 2E).
- A small groove is made in the anteromedial proximal tibial epiphysis under the intermeniscal ligament using a curved rat-tail rasp to bring the tibial graft placement more posterior.
- The free end of the graft is then brought through the joint, under the intermeniscal ligament in the anteromedial epiphyseal groove, and out the medial tibial incision (TECH FIG 2F).

Graft Fixation
- Through the lateral incision, the iliotibial band graft is sutured near the over-the-top position to the intermuscular septum and the periosteum of the posterior lateral femoral condyle with the knee flexed 90 degrees, tension on the graft, and the foot externally rotated 30 degrees (TECH FIG 3A).
- Fluoroscopic imaging is used to assess the location of the proximal tibial physis.
- A longitudinal incision is made in the periosteum distal to the proximal tibial physis.
The edges are gently elevated and a trough is made in the proximal tibial medial metaphyseal cortex.

The knee is flexed 20 degrees and tension applied to the graft.

The graft is sutured to the periosteum at the roughened margins with mattress sutures (TECH FIG 3B).

The knee is checked for stability to Lachman testing and ROM.

### Wound Closure

- The wounds are copiously irrigated.
- The tourniquet is deflated and meticulous hemostasis is achieved.
- The wounds are then closed in layers in a standard fashion.

**TECH FIG 2** • Graft passage for physeal-sparing anterior cruciate ligament reconstruction. A. The graft is brought through the knee in the over-the-top position using a full-length clamp introduced through the anteromedial portal and out the lateral incision. B. Alternatively, a two-incision rear-entry guide can be used. C,D. The lead sutures are used to bring the graft through the notch and out the anteromedial portal. E. After a rasp is used to create a groove in the anterior tibia, under the intermeniscal ligament, a curved clamp is placed under the intermeniscal ligament (F) and the graft is brought to the anterior aspect of the knee. (A,C,E,F: From Kocher MS, Weiss JM. ACL reconstruction in the skeletally immature patient. In Tolo VT, Scaggs DL, eds. Master Techniques in Orthopaedic Surgery: Pediatrics. Philadelphia: Lippincott Williams & Wilkins, 2008:277–287.)

**TECH FIG 3** • Graft fixation for physeal-sparing anterior cruciate ligament reconstruction. A. With the knee flexed 90 degrees, tension on the graft, and the foot externally rotated 30 degrees, the graft is secured to the intermuscular septum and the periosteum of the posterior lateral femoral condyle near the over-the-top position. B. With the knee flexed to 20 degrees, the tensioned graft is secured to the periosteum at the roughened margins of a trough in the proximal tibia. Fluoroscopic imaging is used to ensure that the proximal tibial physis is not disturbed. (A: From Kocher MS, Weiss JM. ACL reconstruction in the skeletally immature patient. In Tolo VT, Scaggs DL, eds. Master techniques in orthopaedic surgery: pediatrics. Philadelphia: Lippincott Williams & Wilkins, 2008:277–287.)
TECHNIQUES

Part 4

Harvest and Preparation of Autogenous Hamstrings Tendon Graft

- Hamstrings are routinely harvested at the start of the case if the diagnosis is not in question. However, if the diagnosis is in doubt, arthroscopy can be performed first to confirm ACL tear.
- The leg is placed in a slightly externally rotated position with the knee slightly bent.
- A 4-cm incision is made over the palpable pes anserinus tendons on the medial side of the upper tibia.
- Dissection is carried through skin to expose the sartorius fascia.
  - The underlying gracilis (superior) and semitendinosus (inferior) tendons are identified by palpation.
  - A longitudinal incision is made in the flat sartorius fascia. The cordlike gracilis and semitendinosus tendons are identified on its deep surface.
  - The tendons are dissected free distally and their free ends whipstitched with no. 2 or no. 5 Ethibond suture.
  - They are dissected proximally using sharp and blunt dissection. Fibrous bands to the medial head of the gastrocnemius should be sought and must be completely released before proceeding with tendon stripping.
  - A closed tendon stripper is used to dissect the tendons free proximally. Firm, steady longitudinal retraction is placed on the tendons individually as the tendon stripper is gently and slowly advanced proximally collinear to the vector of pull of the tendons.
  - Alternatively, the tendons can be left attached distally and an open tendon stripper used to release the tendons proximally.
  - The tendons are taken to the back table and excess muscle is removed by scraping with the side of a no. 15 blade or a Freer.
  - The ends are whipstitched with no. 2 or no. 5 Ethibond suture.
  - The tendons are folded over a closed loop EndoButton.
  - The graft diameter is sized and the graft is placed under tension with wet gauze around it.

Arthroscopy

- Arthroscopy of the knee is then performed through standard anterolateral viewing and anteromedial working portals.

- Management of meniscal injury or chondral injury is performed if present.
- The ACL remnant is excised with the use of biting instruments and the shaver to reveal the anatomic footprint on the tibia and the over-the-top position on the femur.
- Minimal notchplasty is performed to avoid iatrogenic injury to the perichondrial ring of the distal femoral physes, which is very close to the over-the-top position (see Fig 1).

Tibial Tunnel Preparation

- A tibial tunnel guide (set at 50 to 55 degrees) is used through the anteromedial portal.
- The hamstrings harvest incision is used and a guidewire is drilled into the posterior aspect of the ACL tibial footprint.
- The guidewire entry point on the tibia should be kept medial to avoid injury to the tibial tubercle apophysis.
- The guidewire is reamed with the appropriate-diameter reamer based on the size of the graft.
- Excess soft tissue around the tibial tunnel is excised to avoid the formation of a cyclops lesion, which may limit postoperative ROM.
- The posterior rim of the tunnel is smoothed with a rasp to prevent graft abrasion over a sharp tunnel edge.

Femoral Tunnel Preparation

- The transtibial over-the-top guide of the appropriate offset to ensure a 1-mm or 2-mm back wall is passed through the tibial tunnel and hooked around the back wall of the femur in the notch. Rotating the guide and slightly extending the knee help facilitate passage past the posterior cruciate ligament.
- It is rotated to the 10:30 position on a right knee (1:30 on a left knee) and used to pass the femoral guide pin.
- The femoral guide pin is overdrilled with the EndoButton reamer.
- Both are removed and a depth gauge is used to measure the femoral tunnel length.
- The guide pin is replaced and brought through the distal lateral thigh.
- The femur is reamed to the appropriate depth (femoral tunnel length – EndoButton length + 6 to 7 mm to flip the EndoButton).

Graft Passage and Fixation

- The no. 5 Ethibond sutures on the EndoButton are placed in the slot of the guidewire and pulled through the tibial tunnel, through the femoral tunnel, and out the lateral thigh.
- One set of sutures is used to “lead” the EndoButton, while the other set of sutures is used to “follow.” The lead sutures are used to pull the graft through the tibial tunnel and into the femoral tunnel (TECH FIG 4A).
- Once the graft is fully seated in the femoral tunnel, the “follow” sutures are pulled to flip the EndoButton.
(TECH FIG 4B). The flip can be palpated in the thigh, and tension is applied to the graft to ensure that there is no graft slippage.

- The knee is then extended to ensure that there is no graft impingement and cycled about 10 times with tension applied to the graft.
- The knee is flexed to 20 to 30 degrees, tension is applied to the graft, and a posterior force is placed on the tibia.

- On the tibial side, the graft is fixed either with a soft tissue interference screw if there is adequate tunnel distance (at least 30 mm) below the physis to ensure metaphyseal placement of the screw or with a post and spiked washer (TECH FIG 4C,D).
- Fluoroscopy can be used to ensure that the fixation is away from the physis.

POSTOPERATIVE CARE
- Rehabilitation after ACL reconstruction in skeletally immature patients is essential to ensure a good outcome, allow return to sports, and avoid reinjury.
- Rehabilitation in prepubescent children can be challenging. A therapist who is used to working with children and can make therapy interesting and fun is very helpful.
- Compliance with therapy and restrictions should be carefully monitored.
- Weight bearing is limited to touch-down weight bearing for 6 weeks for the physeal-sparing technique and for 2 weeks for the transphyseal technique in adolescents with growth remaining.
- A protective brace is used for 6 weeks postoperatively.
- ROM is limited from 0 to 90 degrees for the first 2 weeks, followed by progressive full ROM.
- A continuous passive motion (CPM) machine from 0 to 90 degrees and cryotherapy are used for 2 weeks postoperatively.
- Progressive supervised rehabilitation consists of ROM exercises, patellar mobilization, electrical stimulation, pool therapy (if available), proprioception exercises, and closed-chain strengthening during the first 3 months postoperatively. A running program that progresses through straight-line jogging, plyometric exercises, and finally sport-specific exercises follows.
- Return to full activity, including cutting sports, is usually allowed at 6 months if the patient has achieved full ROM, has 90% strength compared to the uninjured leg, and can perform a single-leg hop to 90% of the uninjured leg.
- A functional knee brace is routinely used during cutting and pivoting activities for the first 2 years after return to sports.

OUTCOMES
- Performed properly, physeal-sparing combined intra-articular and extra-articular ACL reconstruction using iliotibial band in preadolescent skeletally immature patients appears to provide an excellent functional outcome, with a low revision rate and a minimal risk of growth disturbance.
- The largest study of outcomes after physeal-sparing reconstruction noted a 4.5% revision rate for graft failure at 4.7 and 8.3 years postoperatively, which is comparable to rates for reconstructive procedures in adults (2.3% to 5.3%).
- No cases of significant angular deformity measured radiographically or leg-length discrepancy measured clinically were noted in this series.

COMPPLICATIONS
- Growth disturbance
- Leg-length discrepancy
- Distal femoral valgus
- Tibial recurvatum with an arrest of the tibial tubercle apophysis
- Arthrofibrosis, particularly loss of extension
- Graft failure
- Recurrent instability despite an intact graft, requiring revision to more anatomic reconstruction at skeletal maturity
- Tunnel widening
- Infection
- Deep venous thrombosis

REFERENCES
DEFINITION

- Osteochondritis dissecans (OCD) is a relatively common cause of knee pain and dysfunction in children, adolescents, and young adults.
- OCD is an acquired potentially reversible idiopathic lesion of subchondral bone resulting in delamination and sequestration with or without articular involvement and instability.

ANATOMY

- Initially, softening of the subchondral bone and overlying articular cartilage is noted with an intact articular surface; this can progress to early articular cartilage separation and later osteochondral separation.

PATHOGENESIS

- Although the exact pathogenesis of OCD is unknown, several factors have been historically implicated, including repetitive trauma, ischemia, inflammation, accessory centers of ossification, and genetic factors.
- Overall it is likely that chronic repetitive microtrauma potentially leads to microfractures causing focal subchondral ischemia or alteration of growth. Some patients are believed to have a genetic, biochemical, or behavioral predisposition toward this condition.
- The name “osteochondritis dissecans” implies that this condition has an inflammatory etiology, but further study has not supported inflammation as a primary cause of OCD.
- Although abnormalities in ossification do not account for most cases of OCD as proposed by Ribbing in 1955,16 some incidentally found lateral femoral condyle lesions in younger children that resolve spontaneously may represent ossification variants.
- Based on their anatomic and histologic findings, Green and Banks8 proposed that ischemia was implicated in OCD, although further studies have failed to find a relative ischemic watershed of the lateral aspect of the medial femoral condyle, suggesting that this is not the primary causative factor.
- Petrie14 found OCD in 1 of 86 first-degree relatives, although Mubarak and Carroll15 reported 12 instances of family members with OCD over the course of four generations. While some familial tendencies exist, it is widely believed that the most common form of OCD is not familial.
- In 1933, Fairbanks6 suggested that OCD might be due to a “violent rotation inwards of the tibia, driving the tibial spine against the inner condyle.” Although isolated acute trauma and anterior tibial spine impingement may not be the etiology of lesions in the most common location of the posterolateral aspect of the medial femoral condyle, the frequent occurrence of OCD in patients who are involved in sports with repetitive impact supports a repetitive microtrauma etiology.

NATURAL HISTORY

- Crawford and associates5 followed 21 patients with undetached lesions left in situ with an average follow-up of 7.5 years.
- Healing was noted in the medial femoral condyle in 3 of 10 patients; healing elsewhere was noted in 10 of 11 patients.5

PATIENT HISTORY AND PHYSICAL FINDINGS

- Physical examination findings are often subtle.
- Children and adolescents with stable OCD lesions may walk with a slight antalgic gait.
- In late presentations in which an osteochondral flap or loose body is present, classic biomechanical symptoms including locking, catching, buckling, and giving way may occur.
- With careful palpation through varying amounts of knee flexion, a point of maximal tenderness often can be located over the anterior medial aspect of the knee. The tender area corresponds to the lesion, usually on the lateral aspect of the distal medial femoral condyle.
- With stable lesions, knee effusion, crepitus, and extreme pain through a normal range of motion are rarely observed.
- The Wilson sign may be helpful but is often not present. The Wilson test is performed by starting with the knee flexed to 90 degrees. The tibia is then internally rotated as the knee is extended from 90 degrees toward full extension.
- In a positive Wilson test, pain is elicited over the anterior aspect of the medial femoral condyle. This pain has been described as resulting from contact of the medial tibial eminence with the OCD lesion.
- The mechanical symptoms are more pronounced in the unusual circumstance in which the child or adolescent presents with an unstable lesion. An antalgic gait is common, and there is usually a knee effusion, possibly associated with crepitus, as the knee is taken through a range of motion.
- In stable and unstable presentations, both knees should be examined to determine whether the condition is bilateral. Ipsilateral quadriiceps atrophy may also be noted if the patient has been having pain for more than an extended period of time.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Imaging protocols have received close attention in the literature as a result of the varied success of nonoperative treatment. The goals of imaging are to characterize the lesion, determine the prognosis of nonoperative management, and monitor the healing of the lesion.
- Imaging workup begins with plain radiographs, including anteroposterior (AP), lateral, and tunnel views (FIG 1A–C).
- The tunnel view is particularly valuable since the typical OCD lesion is located on the flexion surface of the lateral aspect of the medial femoral condyle.
A Merchant view should be included to best reveal any OCD lesions of the patella or trochlea.

Plain radiographs usually characterize and localize the lesion and rule out other bony pathology of the knee region.

MRI is most useful for determining the size of the lesion and the status of the cartilage and subchondral bone (Fig 1D,E).

The extent of bony edema, the presence of a high-signal zone beneath the fragment, and the presence of other loose bodies are also important findings on initial MRI.

While less commonly used, technetium bone scans have been employed to provide information about the biologic capacity of an OCD lesion to heal.

**DIFFERENTIAL DIAGNOSIS**

- Irregular ossification
- Acute osteochondral fractures
- Meniscal injuries

**NONOPERATIVE MANAGEMENT**

An initial course of nonoperative management is the treatment of choice for skeletally immature children with small intact lesions.

Controversy exists regarding the ideal nonoperative management for these patients. Clinicians who adhere to treating the subchondral bone as the primary source of pathology favor a period of immobilization. Those whose focus is on the articular cartilage as a source of pathology tend to favor maintaining mobilization.

The options for immobilization include casting, bracing, and standard knee immobilization.

We recommend a three-phase approach to the nonoperative management of OCD lesions.

- Phase I
  - Weeks 1 to 6
  - Knee immobilization in a hinged brace. The patient may walk with the hinged brace locked in extension. The brace may be unlocked to work on range of motion for 5 minutes 5 times per day.

- Phase II
  - Weeks 6 to 12
  - If the patient is pain-free and radiographs show signs of healing after 6 weeks, he or she is allowed to begin weight bearing without immobilization and to begin a physical therapy protocol to improve knee range of motion and quadriceps and hamstring strength.

- Phase III
  - This phase is instituted if the patient continues to remain pain-free and shows radiographic evidence of healing.

  - This phase begins typically 3 months after treatment. Running, jumping, and cutting sports are permitted under close observation.

  - High-impact activities and activities that might involve shear stress to the knee should be restricted until the child has been pain-free for several months and the radiographs show a healed lesion.

  - The goal of nonoperative intervention is to promote healing in the subchondral bone and potentially prevent chondral collapse, subsequent fracture, and crater formation.

**SURGICAL MANAGEMENT**

It is widely accepted that operative treatment should be considered for patients with unstable or detached lesions, and in patients whose lesions have not resolved with an appropriate period of nonoperative management, especially in those approaching skeletal maturity.
Operative treatment is recommended if one or more of the following conditions are met: persistently symptomatic juvenile lesions, the presence of symptomatic loose bodies, predicted physeal closure within 1 year, or fragment detachment.

The goals of operative treatment are to promote healing of subchondral bone, to maintain joint congruity, to fix rigidly unstable fragments, and to replace osteochondral defects with cells that can replace and grow cartilage.

Optimal surgical treatment provides a stable construct of subchondral bone, calcified tidemark, and repair cartilage with viability and biomechanical properties equivalent to or similar to native hyaline cartilage.

Preoperative Planning

Careful preoperative evaluation and preparation are always imperative to the success of treatment.

All imaging studies obtained before surgery should be reviewed. If the avulsed fragment has a relatively large osseous component, then plain radiographs will usually demonstrate the lesion. However, radiographs do not demonstrate the actual size of the cartilaginous component. To demonstrate the cartilaginous component, MRI may be required to determine the extent of the lesion. Any other lesion noted on imaging studies should likewise be addressed.

Positioning

For arthroscopic procedures, the position largely depends on the surgeon’s preference. A variety of positions can be used.

- The leg can be placed in a leg holder on the operating table with the knee joint past the end of the operating table, thus allowing the knee to flex 90 degrees and the lower leg to hang freely.
- The leg can be placed supine on the operating table, with the hip flexed and the knee flexed 90 degrees. The knee can be flexed and the lower leg can in this case hang freely over the side of the operating table.

Approach

Standard arthroscopic parapatellar portals are initially used (FIG 2A).

- Accessory portals may be created higher or lower to the standard parapatellar portals if the lesion is excessively large or in an atypical location.

Transarticular drilling can be used for intact lesions, but it is particularly valuable when the lesion is detached, partially detached, or unstable (FIG 2B).

Epiphyseal drilling is reserved for cases with intact lesions (FIG 2C).

ARThROSCOPIC DRILLING OF INTACT OCD LESIONS

- The knee is exsanguinated and the tourniquet applied.
- An anterolateral portal is made for visualization and an anteromedial portal is made for instrumentation.
- A complete arthroscopic inspection of the knee is performed. Any other pathologies in the knee are recorded and treated accordingly.

Transarticular Drilling

- The lesion is identified (TECH FIG 1A).
- A 0.62-inch Kirschner wire is positioned perpendicular to the lesion (TECH FIG 1B). The portal used depends on the location of the defect.
- The key is to keep the Kirschner wire as perpendicular as possible. Additional portals as well as varying the degree of knee flexion and extension may be used as needed to achieve adequate position.

Transarticular drilling is performed under arthroscopic visualization.

- Appropriate depth of penetration is confirmed by the efflux of blood or fat from the drilled holes (TECH FIG 1C,D).

The drilling should be performed through the calcified tidemark in immature patients, taking care not to penetrate the physis.
**TECH FIG 1** • **A.** The knee is inspected and the lesion is identified. The *solid arrow* shows the intact cartilage side and the *open arrow* shows the osteochondritis dissecans side. **B.** A Kirschner wire is shown superimposed over a T1-weighted MRI. The arrow shows the direction of drilling. The smooth 0.62-inch Kirschner wire should be kept as perpendicular to the lesion as possible to prevent undermining the defect. **C, D.** The appearance of fat or blood demonstrates that subchondral bone has been penetrated.

**Epiphyseal Drilling**

- Once complete inspection has been performed, a 0.62-inch Kirschner wire is directed toward the lesion in a proximal-to-distal direction with fluoroscopic guidance and a guide (**TECH FIG 2**) to help maintain an appropriate angle.
  - The starting point of the Kirschner wire is immediately distal to the physis to avoid any damage.
  - The Kirschner wire is slowly advanced through the subchondral bone, taking care not to penetrate the articular cartilage.
  - The Kirschner wire is kept as perpendicular to the lesion as possible.
  - The position and depth of the Kirschner wires are confirmed using fluoroscopy.
  - Kirschner wires are inserted through the lesion several millimeters apart as needed.
  - Final inspection of the knee is performed and the Kirschner wires and instrumentation are removed.
  - Closure of the knee is performed and sterile dressing is applied before placing the knee in a knee immobilizer.

**TECH FIG 2** • Appropriate guides can be used for antegrade arthroscopic drilling.

**ARTHROSCOPIC DRILLING OF HINGED OCD LESIONS**

- The entire lesion is assessed and the bed is prepared. A débridement is performed until all granulation tissue and sclerotic bone beneath the flap is removed and subchondral bone is reached.
- In deep lesions, autograft or allograft cancellous bone grafting may be required to ensure that the hinged portion of the lesion is not recessed relative to the remaining unaffected cartilage within the knee.
- The lesion is reduced into its bed and fixed with a variety of implants, such as cannulated screws and Herbert screws. The fixation devices may be made of metal or bioabsorbable materials. The implant used depends on the surgeon’s preference.
- We prefer to use small bioabsorbable double-ended threaded compression screws for hinged lesions in which there is appropriate subchondral support (**TECH FIG 3**).
- Once the lesion is secured, drilling may be performed to augment healing.

**TECH FIG 3** • Small bioabsorbable double-ended threaded compression screws are used for hinged lesions in which there is appropriate subchondral support.
ARTHROSCOPIC DRILLING OF UNSTABLE OCD LESIONS

- The knee joint is inspected and loose fragments are removed from the knee joint as necessary (TECH FIG 4A–C).
- The bed of the lesion is inspected and a débridement is performed to remove any granulation tissue and sclerotic bone (TECH FIG 4D–F).
- In reducible lesions, the fragment is prepared as necessary by trimming the edges and securing the lesion into its bed. A variety of implants may be used to secure the lesion based on the surgeon’s preference.
- The joint is inspected before final closure.
- The arthroscopic instrumentation is removed and the arthroscopic portals are closed.
- The knee is placed in a hinged knee brace.

POSTOPERATIVE CARE

- For patients with intact lesions:
  - We use a hinged knee brace in extension or slight flexion for 4 to 6 weeks.
  - Patients are permitted partial (1st week) then complete weight bearing with brace locked in extension.
  - This allows compression to stimulate healing while high-impact running and jumping activities are eliminated.
  - After the hinged brace is removed, patients are sent to physical therapy, where range-of-motion and strengthening exercises are performed.
  - Patients are restricted from running and jumping during weeks 6 through 12.
  - After 3 months repeat imaging (AP, lateral, notch, and tunnel views) is obtained.
  - Healing is typically noted in intact lesions. Occasionally the lesion is not completely healed and another 2 to 3 months of activity restriction are maintained until complete healing.

- For patients with full-thickness lesions:
  - Continuous passive motion (CPM) has been used to enhance the healing of the articular surface in the postoperative period for patients with full-thickness lesions. We prefer 6 weeks of CPM use.
  - CPM was shown to promote articular cartilage healing for moderately small lesions in rabbits (less than 3 mm in diameter). Similar effects were found in humans with predominantly 1- to 2-cm lesions by Rodrigo and colleagues; they reported that CPM for 6 hours per day for 8 weeks produced an improved clinical result.
  - Regardless of the treatment selected, the patient should have a rehabilitation program that combines protection of the compromised articular surface and underlying subchondral bone with maintenance of strength and range of motion.
  - Straight-leg raising and isometric exercises can be performed in the postoperative or immobilization period. In general, the straight-leg raising exercises are performed without resistance initially and advanced by adding 2 to
3 pounds per week, or as tolerated, until 10% of the patient’s body weight is reached.

- A 6- to 8-week home or formal physical therapy program is instituted, incorporating range of motion, stretching, progressive strengthening, and functional or sport-specific training.
- Closed-kinetic-chain exercises are initiated on the sixth week. During this time, the patients are kept out of running and jumping sports but are permitted to perform low-impact activities such as walking, submaximal biking, swimming, and activities of daily living.
- All high-impact activities are limited until 6 months after surgery for those patients treated for full-thickness lesions.
- If patients return to activity before the cartilage has become firm, they will typically complain of pain with maneuvers such as squatting or jumping.

OUTCOMES

- Nonsurgical treatment is often regarded as the treatment of choice for small stable lesions in skeletally immature patients. Typically a period of 3 to 6 months of nonoperative treatment is instituted, with numerous authors reporting a success rate of 50% to 94%.2–4,6–10
- Skeletally immature patients with wide open physes and no signs of instability on MRI are more likely to respond to nonoperative measures.16
- Bradley and Dandy2 reviewed 11 knees in 10 children treated with arthroscopic drilling and found evidence of healing in 9 of 11 knees after 12 months.
- Aglietti and coworkers1 reviewed 14 children (16 knees) treated with transarticular drilling after 1 year of conservative management and found all cases progressed to healing after treatment.
- Kocher and associates10 reviewed 30 knees in 23 patients treated with arthroscopic transarticular drilling after 6 months of conservative therapy. All patients who failed to respond to nonoperative measures were noted to have healed after drilling.

COMPLICATIONS

- Potential failure to heal, especially in older adolescents treated nonsurgically. The prognosis for OCD lesions is worse in those patients who have reached skeletal maturity. Patients who have been treated nonsurgically and have not shown progressive healing and those patients with large lesions that are approaching skeletal maturity are therefore treated surgically to promote healing.

REFERENCES

DEFINITION
- A discoid meniscus is abnormal in both thickness and amount of covering or interposition of the compartment or plateau.
- Over 99% of cases occur on the lateral side of the knee, with an overall incidence of 1% to 15% of the general population.
- Ten percent of children found to have a discoid meniscus will have it bilaterally.

ANATOMY
- Three types of discoid meniscus are described: complete (covering entire compartment), incomplete (on partial compartment covering), and Wrisberg (complete or incomplete compartment covering with no peripheral attachments).5
- Wrisberg type is by definition unstable, allowing displacement, popping, and locking as well.

PATHOGENESIS
- It arises either congenitally or through abnormal development. No cases have been found in autopsies of fetal deaths or stillborns.

NATURAL HISTORY
- Discoid menisci have frequently been found at autopsy in elderly, reportedly asymptomatic people.
- Frequently it is an incidental finding.
- Symptoms typically present in the late first or early second decade of life but may occur at any age.6
- Symptoms are pain with or without loss of motion.

PATIENT HISTORY AND PHYSICAL FINDINGS
- The common presentation is a young child (younger than 10 years) with a catch or popping of the lateral side of the knee with motion, with or without pain.
- Some patients describe true mechanical locking symptoms.
- The patient may present with painful or painless loss of motion.
- The clinical examination may show a hypermobile lateral meniscus with palpable, audible, and frequently visual meniscal instability.
- Effusion is a common finding. Objective signs of swelling with or without activity indicate irritation of the joint and possible tearing.
- Loss of extension and joint line tenderness are also common.4
- A discoid meniscus with a tear or instability will click or pop and may be uncomfortable. The results of the McMurray test will help with diagnosis.
  - Positive: pain and a pop or click
  - Negative: no pain and no pop or click
  - Equivocal: pop or click or pain without the other
  - Significant mobility of the lateral meniscus, while not uncommon, normally may indicate a discoid meniscus.

In children, varus instability may be due to accommodation of the large discoid lateral meniscus. Collateral ligament test results are important.
- Normal: symmetric to the opposite side
- Mild: 1 to 3 mm of increased laxity from the opposite side

IMAGING AND OTHER DIAGNOSTIC STUDIES
- Radiographs may show flattening or sloping of the lateral femoral condyle, with widening of the lateral compartment compared to the medial compartment (FIG 1A).
- MRI will show the discoid meniscus the best (FIG 1B).
  - A discoid meniscus will be thicker and wider than a normal meniscus.
  - Frequently signal change is present in the center of the discoid meniscus; this could represent a tear or degenerative tissue.1
  - There should be no more than three consecutive 3-mm cuts of the body of a meniscus on the sagittal view before it is separated into an anterior and posterior horn. Coronal cuts may also show a wide, thickened meniscus (more than 12 to 15 mm).

FIG 1 • A. Radiographs may show no significant changes, although there may be a widened lateral joint on weight-bearing views, and relative flattening of the lateral femoral condyle may be present. B. MRI shows the discoid meniscus clearly with a thickened, wide meniscus that also has abnormal signal intensity throughout the lateral meniscus.
DIFFERENTIAL DIAGNOSIS
- Meniscal cyst
- Tear in a normal meniscus
- Anterior cruciate ligament tear
- Hypermobile lateral meniscus
- Osteochondritis dissecans
- Patellofemoral instability or dislocation

NONOPERATIVE MANAGEMENT
- If there is no loss of motion or locking, a period of nonoperative management is the first line of defense.
- Nonoperative treatment consists of activity modifications, anti-inflammatory medications, and swelling control (ice, elevation, and compression).
- Patients with intermittent symptoms only that can be controlled with mild doses of nonsteroidal anti-inflammatories are candidates for nonoperative management.

SURGICAL MANAGEMENT
- If locking, loss of motion, or persistent pain and disability exists despite nonoperative management, surgical intervention is indicated.3

Preoperative Planning
- The surgeon should review imaging studies to evaluate the likelihood of a tear or the presence of other pathology.
- The knee examination is repeated under anesthesia, including ligamentous testing, range of motion, and the McMurray test to evaluate whether significant lateral meniscal instability is present.

**ARTHROSCOPIC SAUCERIZATION OF A DISCOID LATERAL MENISCUS**
- After systematic arthroscopic evaluation of the knee is performed, the lateral compartment is opened in the figure 4 position.
- The type of discoid meniscus is determined using a probe sequentially over and under the posterior horn of the meniscus, pulling forward to evaluate displacement.
- Displacement of more than 40% to 50% anteriorly is unstable and requires stabilization with suture fixation.
- Determining peripheral instability may be difficult until the meniscoplasty is at least partly completed.
- Starting in the notch, the free edge of the discoid meniscus is identified (TECH FIG 1A–C).
- May indicate higher likelihood of the Wrisberg type of discoid meniscus.

**Positioning**
- The patient is positioned supine.
- A tourniquet is placed on the proximal thigh of the operative leg over padding.
- A leg holder is placed over the tourniquet.
- The opposite leg is padded and is placed in slight flexion at the hip.
- The foot of the bed is flexed 90 degrees, allowing both legs to flex 90 degrees over the edge of the table.

**Approach**
- Three standard arthroscopic portals are established with a no. 11 blade through stab incisions: inferolateral parapatellar portal for scope visualization, inferomedial parapatellar portal for instruments, and lateral suprapatellar pouch portal for outflow.
- An accessory anterolateral portal may be established for another working portal.
- If the remnant of the discoid meniscus is unstable or torn, requiring fixation or stabilization, a posterolateral approach should be made for inside-out suture fixation.
- A lateral incision is made from the joint line distally by 2 cm, longitudinally in line with the posterior aspect of the fibular head.
- The interval between the biceps femoris and the iliotibial band is entered, as is the space deep to the lateral head of the gastrocnemius.
- A posterior knee retractor is placed in this interval as far medially as possible to protect the neurovascular bundle.
ALTERNATIVE TECHNIQUE FOR MENISCOPLASTY

- The accessory anterolateral portal is made under direct visualization to ensure that there is no inadvertent damage of the peripheral meniscus.
- The free edge of the discoid meniscus is grabbed with an arthroscopic locking grasper through the medial portal.
- A meniscal knife is carefully placed through the accessory lateral portal, ideally with a protective cannula or a sheath.
- Under tension, the discoid meniscus is incised from the anterior notch, leaving about 15 mm of anterior rim, directed toward the junction of the anterior horn and body.
- The surgeon should keep in mind the normal curved architecture of the meniscus.
- At this point the surgeon may need to regrasp the free edge of the discoid meniscus closer to the leading edge of the incised meniscus.
- The knife is then turned to cut along the body of the meniscus.
- The surgeon amputates and removes the flap of the cut discoid, leaving the posterior portion of the discoid left to finish.
- The surgeon piecemeals the remaining excess posterior aspect of the discoid with arthroscopic biters and shaver.
- The remnant is smoothed or thinned with a shaver, biters, or both.

PEARLS AND PITFALLS

| Indications                      |  |
|---------------------------------|  |
| Locking, loss of motion, or persistent pain |  |

| Portal placement                 |  |
|----------------------------------|  |
| Accessory portals are potentially dangerous; they should be placed under direct arthroscopic vision and control. |  |
| A spinal needle is used to identify the level of portal before making the incision. |  |

| Meniscal handling                |  |
|----------------------------------|  |
| The abnormal meniscus is typically difficult to handle arthroscopically owing to its thickness. All the tools at the surgeon's disposal (biters, shaver, meniscal knives) should be used to shape the meniscus. |  |

| Failure to recognize instability |  |
|----------------------------------|  |
| Snapping or pain may be due to a tear of the discoid or an unstable variant. |  |
| It may be difficult to identify some unstable menisci on initial evaluation. |  |
| After saucerization is underway or completed, probing and stability testing are repeated to ensure that an unstable variant or tear is not missed. |  |

| Failure of stabilization         |  |
|----------------------------------|  |
| Stabilization of a congenitally unstable meniscus may fail even with meticulous technique. |  |
| All inside techniques are less successful when used for the lateral meniscus, especially with larger tears. |  |
| Inside-out technique should be used when an unstable or Wrisberg variant is encountered. |  |
| The surgeon should rasp, irritate, or freshen the vascular portion of the meniscus and the synovial lining of the lateral compartment before fixation. |  |

| Leaving the right amount         |  |
|----------------------------------|  |
| The surgeon should aim to leave about 8 mm of meniscus behind. |  |
POSTOPERATIVE CARE

- Weight bearing depends on whether a meniscal repair or stabilization was performed. Immediate weight bearing as tolerated with crutches may be instituted if the discoid meniscus was saucerized only.
- If a stabilization or repair was needed, touch-down weight bearing with crutches, or wheelchair non-weight bearing for young children, is maintained for 4 to 6 weeks.
- Immediate motion (at least 0 to 90 degrees) should be initiated in all children, with full range of motion for saucerization without repair.
- An Ace bandage is used for edema control as needed.
- Bracing is typically not needed. For repairs or stabilizations to limit meniscal stress, a range-of-motion brace (0 to 90 degrees) may be used.
- Physical therapy is useful for obtaining range of motion, as well as initiation of quadriceps activation and strengthening.

COMPLICATIONS

- Infection
- Arthrofibrosis
- Iatrogenic damage
- Subtotal or total meniscectomy
- Nerve or peroneal damage
- Failure of stabilization or repair
- Additional surgery

REFERENCES

DEFINITION
- Femoral anteversion is the angle in the transverse plane by which the neck of the femur is directed (forward) relative to the transcondylar or coronal plane.

ANATOMY
- Femoral anteversion is measured from the projection of the femoral neck axis and the transcondylar axis onto the (transverse) plane perpendicular to the long axis of the femur (FIG 1).
- The terms femoral anteversion and femoral torsion are sometimes used interchangeably, the latter term preferred by those who believe that the orientation of the proximal femur relative to the distal condyles is a consequence of torsion occurring in the shaft of the femur rather than in the neck.6,17,20

PATHOGENESIS
- At birth the femoral anteversion is estimated to be 30 to 50 degrees.
- During normal development, as the child crawls, pulls up to stand, and then walks, hip extension against the anterior iliofemoral ligaments pushes back on the cartilaginous femoral head, gradually decreasing the femoral neck anteversion. The increased anteversion of infancy “unwinds” spontaneously with growth.
- This natural remodeling process may be impaired because of abnormal hip anatomy, developmental delay, abnormal muscle tone, or ligamentous laxity, resulting in the persistence of the increased anteversion of infancy.21
- Increased anteversion has been associated with a number of clinical conditions, including cerebral palsy, developmental hip dysplasia, and Perthes disease.2,7,12,24

NATURAL HISTORY
Physiologic Anteversion
- In some children the increased anteversion of infancy may persist without any other identifiable pathology. This is the most common cause of in-toeing in children. Most of these cases resolve spontaneously with growth by the time of puberty.7
- In a few children, anteversion persists into adolescence. Most children compensate well and only in a small minority does this interfere with their gait or physical function.

Cerebral Palsy
- Cerebral palsy is associated with developmental delay. By the time the child stands or walks, the more ossified femoral head and neck is less likely to remodel in response to increasing hip extension. This may be further compromised because of the presence of hip flexion contractures. Furthermore, spasticity of the muscles that internally rotate the femur, such as the medial hamstrings and anterior gluteals, may contribute to the development of increased anteversion. Consequently, the increased anteversion of infancy may persist or even increase.
- To seat the femoral heads congruously within the acetabulum during walking, the limb is internally rotated and the pelvis tilted anteriorly (increased lumbar lordosis), resulting in significant gait anomalies.8
- In the face of increased femoral anteversion, the greater trochanter and the insertion of the gluteus medius are located more posterior. This effectively reduces the abductor lever arm.1
- In children with severe nonambulatory cerebral palsy, the increased anteversion and coxa valga are features of the hip at risk for dislocation.
- Increased anteversion is a component of “miserable malalignment syndrome,” which has been implicated as a source of patellofemoral pain and instability.5,13
- There is conflicting evidence linking abnormally increased or decreased femoral anteversion with osteoarthritis of the hip and knee.2,6,27
- Slipped capital femoral epiphysis has been associated with decreased anteversion or even retroversion.9

PATIENT HISTORY AND PHYSICAL FINDINGS
- This is a common cause for in-toeing in children.
- Children are more likely to sit in the W position and may not be able to sit cross-legged (FIG 2). This is because their hips can rotate internally more than they can rotate externally.
- Normal foot progression angle during walking is 5 to 10 degrees external. Internal foot progression angle accompanied by medial or internal rotation of the knee is attributable to increased internal rotation at the hip associated with increased femoral anteversion.
- Normal or even abnormal external foot progression angle may be present in the face of increased femoral anteversion when it is accompanied by excessive external tibial torsion.
- Examination of the torsional profile in the prone position indicates the presence of increased femoral anteversion. The
Part 4 PEDIATRICS • Section III RECONSTRUCTION

The magnitude of anteversion can be quantified by physical examination using the palpable prominence of the greater trochanter as a proxy for the femoral neck axis. This method, first described by Netter, was adapted by Ruwe and associates, who also described an intraoperative method to estimate anteversion that could be applied at the time of derotational osteotomy of the proximal femur. The accuracy of the physical examination method has been evaluated by Davids and coworkers.3

IMAGING AND OTHER DIAGNOSTIC STUDIES

A number of imaging techniques have been described to estimate femoral anteversion, including plain radiography, CT, ultrasonography, and MRI (FIG 3).

DIFFERENTIAL DIAGNOSIS

Increased anteversion is encountered in the following situations:

- Physiologic anteversion
- “Miserable malalignment syndrome”
- Cerebral palsy
- Developmental hip dysplasia
- Legg-Calvé-Perthes disease

NONOPERATIVE MANAGEMENT

Attempts to treat increased femoral anteversion with twister cables and other braces have been abandoned as the natural history of spontaneous remodeling came to be understood.22

SURGICAL MANAGEMENT

Indications

- Increased anteversion with severe medial rotation of the lower extremity and increased internal foot progression angle that has failed to resolve by adolescence, and is interfering with gait and function due to tripping
- Increased femoral anteversion associated with increased external tibial torsion and genu valgum, the so-called miserable malalignment syndrome when it is associated with patellar instability or patellofemoral pain refractory to nonoperative methods of treatment
- Increased femoral anteversion in children with ambulatory cerebral palsy, in whom the increased internal rotation of the hip results in significant abductor “lever arm dysfunction,” leading to impaired gait efficiency, instability, and tripping. Increased femoral anteversion may be accompanied by increased external tibial torsion, which must be simultaneously addressed with internal tibial derotational osteotomies to optimize the ultimate foot progression angle while walking.
- Increased anteversion along with coxa valga is a component of the abnormal proximal femoral anatomy in longstanding cases of congenital, developmental, or neurogenically acquired hip dislocations. In these instances, the proximal femoral derotational osteotomy is combined with varusization of the femoral neck. The proximal femoral varus derotational osteotomy is described in Chapter PE-27.

Preoperative Planning

Preoperative planning involves quantifying the extent of the femoral anteversion in order to guide the extent of derotation required.

- Assessment of the torsional profile of the entire limb is critical because any proximal corrections will result in distal consequences if distal torsional malalignments are not taken into consideration and concurrently addressed.
- In most children physical examination by the method described above is adequate to detect the presence of increased anteversion and to quantify it accurately enough to guide surgical correction. Generally, preoperative axial imaging such as CT scan is unnecessary, as the magnitude of intraoperative corrections is also based on the physical examination technique.
- In children with ambulatory cerebral palsy whose femoral anteversion is possibly one of a number of multilevel lower extremity soft tissue and bony abnormalities, there may be great value in conducting a 3-D gait analysis. Gait analysis provides a dynamic assessment that can provide useful transverse plane kinematics and kinetics to help guide the decision regarding the need for and amount of derotation.
- Plane radiographs are important, including an anteroposterior (AP) view of the pelvis to include the proximal femurs and frog-leg lateral views of each proximal femur.

FIG 2 • W-sitting (A) is easier than sitting cross-legged (B) for children with increased femoral anteversion.

FIG 3 • CT method of estimating femoral anteversion involves overlapping images of three slices: the femoral head, the femoral neck at the base, and the distal femur through the femoral condyles.
Positioning
- The supine position is preferred when other operations necessitating this position are necessary, such as intramuscular psoas lengthening, pelvic osteotomies, or rectus femoris transfers (FIG 4A).
- The prone position has the advantage of permitting the same intraoperative assessment of the torsional profile as the preoperative assessment (FIG 4B,C). The exposure is facilitated by the reflected vastus lateralis falling away from the field of surgery owing to gravity.
- The prone position allows other concomitant operations to be performed, such as posterior knee (hamstring lengthening) or posterior calf surgery.
- This position does not permit anterior pelvic or hip surgery.

Approach
- Standard lateral approach to the proximal femur

PROXIMAL FEMORAL DEROTATIONAL OSTEOTOMY WITH 90-DEGREE AO BLADE PLATE: SUPINE TECHNIQUE

Positioning, Incision, and Exposure
- The patient is positioned supine on the radiolucent table.
- The image intensifier is set up perpendicular to the long axis of the table, from the contralateral side, to obtain clear AP and frog-leg lateral images of the proximal femur.
- Both lower extremities are prepared and draped free to permit assessment and comparison of the torsional profile.
- A longitudinal incision is made along the lateral aspect of the proximal thigh starting at the level of the greater trochanteric prominence and extended distally for about 10 to 12 cm in line with the femur.
- The underlying fascia lata is divided in line with the skin incision to expose the vastus lateralis and the overlying bursa at the level of the greater trochanter.
- The vastus lateralis is divided transversely at its origin on the trochanteric ridge, which corresponds to the inferior level of the insertion of the gluteus medius anteriorly (TECH FIG 1A).
- The vastus lateralis separation is continued inferiorly in an L-shaped manner along its posterior margin just anterior to the insertion of the gluteus maximus (TECH FIG 1B).
To minimize injury to the muscle belly, the thin fascia over the vastus lateralis is divided along the posterior margin close to the linea aspera, and the muscle is peeled off the septum with a broad elevator or cautery until the subperiosteal surface of the lateral aspect of the proximal femur is exposed (TECH FIG 1C).

Care is taken to identify and cauterize the perforators as they are encountered.

The vastus lateralis is then elevated subperiosteally until the lateral surface of the femur is adequately exposed for sufficient distance to accommodate the length of the blade plate (TECH FIG 1D).

At the level of the planned osteotomy, at the upper end of the lesser trochanter, the periosteum is elevated circumferentially with a narrow curved elevator.

The transverse osteotomy at this level heals rapidly and permits the use of strong internal fixation (blade plate), obviating the need for casting or any other external immobilization.

Preparation for Osteotomy and Fixation

Using the image intensifier, a guide pin is inserted through the middle of the superior portion of the proximal femoral neck at an angle that is 90 degrees to the long axis of the femur.

An effective way of ensuring that the initial guide pin is in the middle of the femoral neck axis in the transverse plane is to internally rotate the lower extremity and hip until the prominence of the greater trochanter is directly lateral. This usually occurs when the neck axis has been horizontalized.

With the lower extremity held in this position, the guide pin can be inserted parallel to the floor.

Because the greater trochanter is set slightly posterior relative to the neck axis, the starting point is best made in line with the middle of the AP width of the femur just distal to the greater trochanter.

On the AP image the guide pin needs to be sufficiently proximal (superior) to provide enough room to permit the introduction of the seating chisel inferior to the guide pin (TECH FIG 2A).

On the frog-leg lateral view, the guide pin should lie in the middle of the femoral neck in line with the neck axis (TECH FIG 2B).

The seating chisel is then used to create the hole in the bone to accommodate the blade plate.

Depending on the age of the child and the size of the bone, the matching seating chisel corresponding to the appropriately sized blade plate is used (infant, toddler, child, adolescent, or adult).

The seating chisel must be inserted perpendicular to the long axis of the femur if derotation is the only objective (TECH FIG 2C). Any deviation from the perpendicular on the AP view will lead to varus or valgus changes in the neck-shaft axis.

The face of the seating chisel should also be perpendicular to the long axis (in the sagittal plane) to prevent unintended flexion or extension through the osteotomy (TECH FIG 2D).

The direction of the seating chisel for the blade plate can be adjusted if the guide pin is not perfectly aligned.

Alternatively, if a cannulated seating chisel is available, the guide pin must be placed in the correct position for the seating chisel.

The disadvantage of a cannulated system is that there is no room for error in the placement of the guide pin. Furthermore, the blade plate itself is not cannulat-
lated, which necessitates removal of the guide pin (in addition to the seating chisel) at the time of insertion of the blade plate, which removes an important guide for its introduction.

- The seating chisel is advanced up to the depth of the selected blade length. The depth in millimeters of the seating chisel is marked on its inferior surface.
- In older ambulatory children with healthy bone, the seating chisel should be intermittently backed out to prevent its impaction in the strong bone.
- It is prudent to back the chisel out, short of its final resting position, before completion of the osteotomy to facilitate its removal in exchange for the blade plate (TECH FIG 2E).

**Osteotomy**

- The level of the transverse osteotomy is marked on the bone with a marking pen or cautery. This is done about 1 to 1.5 cm below the level of the seating chisel, at the upper end or just proximal to the lesser trochanter (TECH FIG 3A).
- The periosteum is elevated circumferentially at this level to allow placement of protective retractors during the osteotomy.
- Two smooth pins (2.5-mm Kirschner wires) are placed in an anterior-to-posterior direction parallel to each other and perpendicular to the long axis, just proximal and distal to the proposed osteotomy site respectively (TECH FIG 3A).
- These two pins will serve as useful retractors of the vastus lateralis muscle anteriorly, and as joysticks to retain effective control of the proximal and distal segments after the osteotomy.
- At the time of the derotation, the angle between the distal and proximal pins accurately gauges the magnitude of correction obtained and maintained during fixation of the blade plate.
- The transverse osteotomy is completed with an oscillating saw directed perpendicular to the long axis of the femur and parallel to the seating chisel above (TECH FIG 3B, C).

**Derotation and Fixation**

- The seating chisel is removed in exchange for the matching 90-degree blade plate of appropriate blade length (TECH FIG 4A).
- The blade is inserted manually into the seating hole using thumb pressure. The blade plate holder is struck with a mallet to advance the blade until the plate lies adjacent to the lateral surface of the femur (TECH FIG 4B).
- The plate is held against the distal segment of the femur using a plate-holding clamp such as the Verbrugge clamp (TECH FIG 4C).
- Before securing the plate, the lower extremity (along with the distal femoral segment) is externally rotated by the desired angle of derotation that can be estimated by the position of the distal pin relative to the proximal pin (TECH FIG 4D).
- Since the guide pin in the femoral neck has been placed along the middle of the neck axis, it is relatively simple to estimate the new femoral anteversion.
- If the lower extremity is held with the patella positioned anteriorly, then the angle between the femoral neck guide pin and the horizontal plane is the new angle of femoral anteversion.
- Once the desired degree of derotation has been set, the plate is secured to the bone with standard fully threaded...
The plate is held against the femur with a plate-holding (Verbrugge) clamp. The distal fragment is externally rotated by the desired amount using the two AP pins to judge the angle of correction. The plate is secured with cortical screws and the osteotomy is compressed. An impacter is used to advance the blade plate to its full depth. AP view of the proximal femur. Frog-leg lateral view of the proximal femur.

C. After fixation with the first screw, the arc of rotation is estimated (with the hip extended) using the guide pins to quantify the amount of internal and external rotation from the neutral position.
D. At least two of the screws are placed eccentrically to compress the osteotomy site.
E. The impacter is used to advance the blade plate to its full depth.
F. The guide pins are removed and AP and frog-leg lateral images obtained to confirm satisfactory position of the blade plate.
G. Wound Closure
H. 

Wound Closure
- The vastus lateralis is reattached to its origin on the trochanteric ridge with absorbable braided 0 suture so that the entire plate is covered (TECH FIG 5). Two or three tacking sutures are used to reattach the posterior edge of the vastus fascia to the septum.
- The wound is closed in layers, including the fascia lata, the subcutaneous tissue, and the skin. Absorbable running subcuticular suture will obviate the need for suture removal.
- The patient is positioned prone on appropriate (low) bolsters to support the chest and iliac crests, keeping pressure off the abdomen and the genitalia.
- The table mattress padding under the thigh segments can be built up to keep the hips relatively extended.
- The approach and dissection are identical to those described for the supine technique; only the orientation must be remembered with the anterior vastus lateralis now falling away from the operative field (TECH FIG 6A).
- The torsional profile in the prone position is much easier to verify and compare with the contralateral side (TECH FIG 6B, C).
Chapter 26  PROXIMAL FEMORAL ROTATIONAL OSTEOTOMY  1193

TECH FIG 6 • Proximal femoral derotation osteotomy using the prone technique. A. Orientation of the exposure in the prone position. B, C. Intraoperative ability to estimate the torsional profile.

PROXIMAL FEMORAL DEROTATIONAL OSTEOTOMY WITH A REGULAR LOW-CONTACT DYNAMIC COMPRESSION (LCDC) PLATE

- Using the identical approach described above, the derotational osteotomy can be stabilized with a regular LCDC plate.
- For secure fixation, the osteotomy would have to be done lower, in the subtrochanteric region, to allow a sufficient number of screws (at least three) proximal to the osteotomy.
- The fixation is not as strong as that afforded by a blade plate but might be adequate in most children.
- This is not a good technique if derotation of the proximal femur is combined with varusization for hip instability.

DISTAL FEMORAL DEROTATIONAL OSTEOTOMY

- There is controversy about whether a distal or proximal femoral osteotomy is the optimal method to address abnormal femoral torsion or anteversion.
- The distal femoral derotational osteotomy is described elsewhere.

PEARLS AND PITFALLS

<table>
<thead>
<tr>
<th>Preoperative planning</th>
<th>Assessment of the complete torsional profile is essential to prevent unintended postoperative consequences.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Orientation of 90-degree blade plate</td>
<td>The seating chisel and the blade plate must be introduced at right angles to the long axis of the femur both in the coronal and sagittal planes, if derotation is the only goal.</td>
</tr>
<tr>
<td></td>
<td>Any significant deviation in the orientation of the blade plate in the coronal plane will result in unintended varus or valgus.</td>
</tr>
<tr>
<td></td>
<td>Any significant deviation in the orientation of the blade plate in the sagittal plane will result in unintended flexion or extension.</td>
</tr>
<tr>
<td>Orientation of osteotomy</td>
<td>The orientation of the transverse osteotomy must also be at right angles to the long axis of the femur both in the coronal and sagittal planes, if derotation is the only goal.</td>
</tr>
<tr>
<td></td>
<td>The osteotomy should be made parallel to the seating chisel.</td>
</tr>
<tr>
<td>Derotation technique</td>
<td>The use of two parallel anteroposterior guide pins placed just proximal and distal to the line of the osteotomy provides an excellent guide to judge the magnitude of derotation, while providing a joystick to fine-control the position of the fragments at the time of fixation. This is particularly useful when using the supine technique, where the femoral anteversion and correction are more difficult to estimate.</td>
</tr>
<tr>
<td></td>
<td>The two pins also provide useful retraction of the overhanging muscle belly of the vastus lateralis when the supine position is used.</td>
</tr>
</tbody>
</table>
**POSTOPERATIVE CARE**

- With secure blade plate fixation, external immobilization is seldom if ever required. External immobilization in the form of a below-knee cast or a knee immobilizer may be indicated for concomitant procedures, but not for the femoral derotational osteotomy per se.
- Touch-down weight bearing (no more than the weight of the lower extremity) is permitted on the affected lower extremity.
- If the procedure is done bilaterally, the child is unable to bear weight safely and a wheelchair is required.
- Depending on the age and ambulatory status of the child, progressively increased weight bearing is permitted from 4 to 6 weeks postoperatively.
- Supported weight bearing in a pool may be possible as early as 3 weeks postoperatively.
- Once there is clinical and radiographic evidence of union and consolidation of the osteotomy, all restrictions can be lifted (FIG 5).

**OUTCOMES**

- Little is known about the long-term outcomes of femoral derotational osteotomies, as these are seldom done in isolation.
- If adequate correction is achieved, ambulatory patients can expect to experience noticeable benefits in the appearance of their gait. Whether there are measurable functional improvements is less clear.
- In conditions like cerebral palsy, the primary pathology in the brain cannot be addressed. Consequently, the abnormal forces that created the increased anteversion in the first place may contribute to its recurrence in the growing child.
- There is no clear indication for routine removal of hardware.

**COMPLICATIONS**

- Undercorrection
- Overcorrection
- Unrecognized or unaddressed abnormal tibial torsion
- Recurrence

**REFERENCES**

Proximal femoral varus osteotomy can be useful for many conditions:
- Coxa valga deformity
- Hip subluxation (nearly all etiologies)
- Containment for Perthes disease
- Degenerative arthritis
- Correction in other planes can be accomplished simultaneously (derotation and extension–flexion). Proximal femoral varus osteotomy can be accomplished at any age as satisfactory implants are available for all bone sizes.
- In some situations (eg, neuromuscular disease), it may be necessary to address the etiology of the proximal femoral deformity and hip disease simultaneously.

ANATOMY
- The normal femoral neck–shaft angle is 135 degrees (range 120 to 150 degrees).
- The true neck–shaft angle cannot be directly assessed from an anteroposterior (AP) pelvis radiograph unless femoral anteversion is compensated for by internally rotating the femur to eliminate it.
- The tip of the greater trochanter is at the level of the center of the femoral head.
- The neck–shaft angle at birth is typically 150 degrees, decreasing to 135 degrees by skeletal maturity.
- Normal anteversion at birth is 45 degrees, decreasing to 10 degrees in boys and 15 degrees in girls by 8 years of age.

PATHOGENESIS
- The development of normal femoral anatomy and resolution of fetal bone alignment requires the attainment of gross motor activities at a typical age and is dependent on normal musculoskeletal forces. Both of these can be affected by neuromuscular conditions such as cerebral palsy or myelomeningocele.
- Patients with Perthes disease may have a subluxated or uncovered femoral head even with proximal femoral anatomy that is normal except for the avascular femoral head segment. Even so, with good neuromuscular function, varusizing the femur can be well tolerated and can improve the containment of the diseased femoral head.
- Contributing factors to the hip joint pathology may include musculotendinous contractures, ligamentous laxity, and coexistent acetabular dysplasia. If present, these may also require direct treatment. Adductor lengthening, psoas lengthening, open reduction of the hip with capsulorrhaphy, and acetabuloplasty may need to be considered.
- Excessive ROM indicates relative ligamentous laxity.
- Shifted ROM (eg, excessive internal ROM) indicates excessive femoral anteversion.
In adolescents and young adults being evaluated for early degenerative arthrosis, pain may be found at the extremes of ROM. Severe ROM restrictions could be a contraindication to consideration of realignment osteotomy in these cases.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- A plain AP pelvis radiograph with anteversion eliminated is diagnostic of coxa valga.
  - If anteversion is normal, no compensation for hip rotation is necessary.
  - If anteversion is excessive, the AP pelvis radiograph should be taken with the hip internally rotated to obtain a true AP view of the proximal femur.
  - Acetabular dysplasia should be ruled out.
  - Hip subluxation or femoral head uncoverage is assessed. Signs of degenerative arthrosis are sought.
- CT scans (including three-dimensional reconstruction) are not useful or needed for primary proximal femoral deformities but can be helpful in evaluating acetabular dysplasia or potentially in revision cases.
- MRI may be useful in evaluating associated problems, including labral tears, hip joint effusions, narrowing of articular cartilage, and femoral head vascularity.

**DIFFERENTIAL DIAGNOSIS**

- Hip joint contracture
- Hip joint subluxation
- Femoral anteversion or retroversion
- Musculotendinous contracture
- Acetabular dysplasia

**NONOPERATIVE MANAGEMENT**

- Nonoperative management may be helpful for one of the associated conditions listed above.
- There is no nonoperative treatment for bone deformity that is clinically significant and adversely affecting hip joint development.

**SURGICAL MANAGEMENT**

**Preoperative Planning**

- The AP pelvis radiograph is reviewed.
- The size of implant is chosen based on radiographic templates.
- The amount of varusization can be determined based on radiographs preoperatively or on intraoperative findings. Other associated problems (musculotendinous contracture, joint instability, and acetabular dysplasia) are addressed concurrently.
- There is no examination under anesthesia to determine the amount of varusization to accomplish. An examination under anesthesia can guide decision making regarding concurrent tendon lengthening.
- Varusization will inevitably shorten the extremity. The effect on leg length can be controlled by altering the amount of varusization and the size of the wedge of bone removed (if any) depending on preoperative leg-length assessment. Varus can be accomplished using a medial closing or lateral opening osteotomy.

**Positioning**

- Although some surgeons prefer to perform proximal femoral varus osteotomy with the patient supine, I prefer the prone position with the leg draped free (FIG 1).
  - This allows ease of exposure posterior to the muscle belly of the vastus lateralis.
  - The prone position also allows accurate control of femoral torsion comparable to the prone physical examination for femoral anteversion by palpation, thereby improving consistency of surgical realignment.

**Approach**

- A direct lateral approach to the proximal femur is routine. The procedure involves placing the chisel for the blade plate in the appropriate position in the femoral neck corresponding to the amount of varus to accomplish (eg, 20-degree varus correction corresponds to 70-degree chisel placement relative to the lateral femoral cortical surface: 90-degree blade plate minus 70 degrees equals 20 degrees varusization), completing the osteotomy, and placing the 90-degree blade plate as detailed in the Techniques section.

**FIG 1** Prone positioning allows easy access to divide the vastus lateralis posteriorly and replicates the position for physical examination for femoral anteversion, allowing improved accuracy and reliability of assessment and correction of femoral torsional alignment.
EXPOSURE

- A longitudinal lateral incision is made over the proximal femur matching the length of the blade plate.
- The fascia lata is divided in line with the skin incision (TECH FIG 1A).
- The vastus lateralis is reflected from its proximal and posterior origins and elevated to expose the proximal femur subperiosteally.
- Circumferential subperiosteal elevators are placed in the intertrochanteric area to protect the soft tissues (TECH FIG 1B).

GUIDEWIRE PLACEMENT

- A fluoroscope is used to guide placement of a guidewire in both the AP and lateral views.
- The entry point is just below the greater trochanteric apophysis if the patient is skeletally immature and through the greater trochanter after maturity.
  - The entry point is chosen to allow insertion of the guidewire and chisel without violating the medial calcar.
- The anterior-to-posterior placement is determined in the view obtained by flexing the hip and knee (with the knee over the edge of the operating table) and internally and externally rotating the hip until the fluoroscopic image shows the femoral neck and femoral shaft colinear with the guidewire placed centrally and parallel to the neck and shaft of the femur (TECH FIG 2A).
- The orientation of the pin on the AP view is controlled with an osteotomy triangle (TECH FIG 2B,C).
- If preoperative planning indicated a 15-degree varusization goal, a 75-degree triangle would be used (see the Approach section above).
- Alternatively, determination can be made based on preoperative and desired postoperative alignment; for example, the preoperative neck-shaft angle (150 degrees) minus the desired postoperative neck-shaft angle (120 degrees) equals 30 degrees of varusization. In this case, the guidewire would be placed at a 60-degree angle to the femoral shaft when using the 90-degree plate.
- The anteversion is determined (transverse plane) by the angle between the pin (placed as described above) and the tibial shaft (perpendicular to the posterior aspect of the femoral condyles when the knee is flexed, provided there is no tibial varus or valgus).
PLACEMENT OF THE BLADE PLATE CHISEL

- The appropriate-size chisel for the blade plate is then placed just below and exactly parallel to the pin to the desired depth (greatest depth possible depending on anatomy and available length of the blade plate; TECH FIG 3).
- The chisel should be dislodged 5 to 10 mm before the osteotomy to allow for ease of later removal.

PERFORMING THE OSTEOTOMY

- The details of the osteotomy are based on preoperative planning.
- To minimize the shortening effect of the osteotomy on leg length in a child, a single transverse osteotomy can be performed in the intertrochanteric area (TECH FIG 4).
- This will result in a lateral opening osteotomy.
- Alternatively, a wedge of bone can be removed to accomplish a medial closing osteotomy.

Wedge Osteotomy

- The first osteotomy is performed parallel to the chisel.
- The entry point for the osteotomy saw blade is determined by the implant (distance between the blade and the subsequent angle in the plate for medialization).
- A second osteotomy is then performed perpendicular to the femoral shaft.
- The starting level for this osteotomy varies depending on the desired amount of shortening of the extremity.
- A beginning point identical to the entry point for the first osteotomy achieves full contact of the osteotomy after fixation.
- A lateral starting level distal to the first removes a portion of the lateral femoral cortex, achieving more shortening, but is limited by the insertion of the psoas tendon on the lesser trochanter (typically should not be violated).
- An entry point proximal (within the cut of the first osteotomy) leads to less shortening, but incomplete final apposition of the osteotomy surfaces.
**PLACEMENT OF THE BLADE PLATE**

- Realignment and fixation of the osteotomy are achieved by placing the blade plate.
- The chisel is removed and the blade plate is placed in the chisel path parallel to the guidewire and impacted to its final position (TECH FIG 5A).
- The femoral shaft is reduced to the plate and held in position with a Verbrugge clamp (TECH FIG 5B).
- Final anteversion alignment is controlled at this point (TECH FIG 5C).

- The first two screws are typically placed in compression to optimize fixation and promote rapid healing (TECH FIG 5D).
- Alignment is checked after placement of the first screw both radiographically and by physical examination.
- If satisfactory, the final screws are placed. If not, alignment is adjusted accordingly.
- Final radiographs are taken in both views (TECH FIG 5E,F).
- The wound is closed in layers.

**TECH FIG 5** • A. The chisel has been replaced with the blade plate (guidewire is still in place). B. Correction of deformity by reducing the plate to the femoral shaft with a Verbrugge clamp. C. Anteversion is assessed before guide pin removal (corrected to 10 degrees). D. Fixation is complete (note well-apposed osteotomy surfaces). E,F. Postoperative AP and lateral views confirming implant placement, proper osteotomy alignment, and appropriate medialization of the femoral shaft to align the piriformis fossa with the intramedullary canal.

| Accurate realignment | Prone positioning promotes accurate control, correction, or both of femoral torsion. |
| Final alignment depends only on the angle of pin insertion and the choice of blade plate angle (in this case, 90 degrees). |
| Apposition of the osteotomy surfaces themselves also depends on the orientation of the osteotomy cuts. |
POSTOPERATIVE CARE
- Weight-bearing status and immobilization depend on patient age, condition being treated, compliance, bone size, implant size, and bone quality.
  - Weight bearing can vary from toe-touch to non-weight bearing for the first 3 to 6 weeks.
  - With poor bone quality, small bone size, small implant size, or poor compliance, a spica cast should be applied.
  - In intermediate situations, bilateral short-leg casts with a Dennis Brown bar can be applied along with knee immobilizers (Fig 2).
  - Unrestricted range of motion without external immobilization may be allowed (eg, most adults).
  - A range-of-motion and strengthening program often is instituted at 3 to 4 weeks postoperatively.
  - Advancement to full weight bearing can be accomplished within 6 to 8 weeks of the procedure, depending on muscle strength.

OUTCOMES
- Patients over 8 years of age with moderate Perthes disease (lateral pillar B or B/C border) have a better outcome with surgery.2
- The complex spectrum of cerebral palsy hip subluxation, hip dysplasia, and dislocation can be treated successfully in most cases using a treatment algorithm that incorporates femoral varus and derotation osteotomy. While there is a risk of recurrence and complications, McNerney and associates3 reported excellent results with aggressive surgical management with a low rate of complications and repeat acetabuloplasty or varus osteotomy.

COMPLICATIONS
- Excessive varusization leading to hip abductor insufficiency
- Implant failure
- Malunion
- Nonunion
- Deep venous thrombosis in adults
- Infection
- Avascular necrosis
- Implant irritation contributing to Trendelenburg gait
- Overcorrection or undercorrection

REFERENCES
DEFINITION

- The term proximal focal femoral deficiency (PFFD) is used to describe congenital femoral deficiency and deformity of the proximal femur to be distinguished from the congenital short femur.6 However, the more comprehensive term congenital femoral deficiency (CFD)13 better describes the spectrum of deficiency, deformity, and discrepancy ranging from the congenital short femur to the most severe PFFD.
- The severity of the deformity varies widely, and this condition can be diagnosed in the prenatal period using ultrasound examination.11
- In most cases, CFD is not simple coxa vara. Patients with CFD lack integrity, stability, and mobility of the hip and knee, with concurrent joint malorientation, bony deformity, and soft tissue contractures. The affected limb grows at an inhibited rate depending on the severity of the underlying deficiency. The resulting limb-length discrepancy (LLD) can be accurately predicted using the multiplier method.1,2,10

ANATOMY

- Although existing classification systems for PFFD are descriptive, these classification systems are not helpful in determining the final femoral morphology or treatment strategies.13
  - The Paley classification system (FIG 1) is based on factors that reflect the severity of pathology and reconstructability of the congenitally deficient femur. This classification is based on pathologic factors that determine surgical reconstruction strategies.8
  - The abnormal anatomy of CFD consists of coxa vara of the proximal femur with abduction contracture of the hip (ie, tensor fascia lata [TFL], gluteus medius, and gluteus minimus muscles), proximal femoral extension deformity (flexion in some cases) with concurrent hip flexion contracture (ie, rectus femoris, TFL, and psoas muscles), and external femoral torsion–retroversion with concurrent external soft tissue contracture (ie, piriformis muscle).
  - The proximal femur can also present a region of delayed ossification in either the subtrochanteric region or the neck region. Ossification of the cartilaginous proximal femur differentiates Paley type 1a CFD (ie, normal ossification) from Paley type 1b CFD (ie, delayed ossification) (FIG 1).
  - Once treated with realignment of the proximal femur, these regions of delayed ossification in the type 1b hip begin to ossify (the regions do not always fully unite), converting the hip into type 1a. This area of delayed ossification is often mistaken for a pseudarthrosis (it could be referred to as a stiff cartilaginous pseudarthrosis to differentiate it from type 2, in which there is a true mobile, fibrous pseudarthrosis).
  - A more severe form of CFD is classified as Paley type 2; this type has a true mobile pseudarthrosis between the greater trochanter and femoral head or complete absence of the femoral head (FIG 1).

- The most severe proximal deficiencies are classified as Paley type 3 (diaphyseal deficiencies). In these cases, the greater trochanter is absent and the knee joint is affected to a greater extent. Complete absence of the femur is included in this group.
- In very rare cases, there is a distal deficiency of the femur (ie, Paley type 4). Cases of distal deficiency present with very severe knee varus but a well-developed, intact hip joint.
- Acetabular dysplasia is almost always present in patients with CFD. This deformity must be recognized and corrected to prevent subluxation or dislocation of the hip during lengthening.
- Congenital knee abnormalities also exist with CFD. Absent or hypoplastic cruciate ligaments (ie, anterior cruciate ligament [ACL], posterior cruciate ligament [PCL]), hypoplastic lateral femoral condyle resulting in genu valgum, and hypoplastic patella with lateral maltracking, subluxation, or dislocation are common. Rotatory instability of the tibiofemoral joint and knee flexion contractures (ie, biceps femoris muscle, posterior knee joint capsule, iliotibial band) are also common.

PATHOGENESIS

- The cause of an isolated single-limb abnormality is usually unknown. CFD is usually not related to a genetic syndrome. This is in contrast to radial clubhand, tibial hemimelia, or multiple limb deficiencies.
- A patient with CFD presenting for initial evaluation does not require a genetic consultation unless multiple limb deficiencies or other congenital malformations are present.

NATURAL HISTORY

- The natural history of CFD is a progressive LLD in unilateral cases. The deformities and soft tissue contractures described above persist but do not progress.
- The Paley type 1b hip shows eventual ossification of the cartilaginous femoral neck or subtrochanteric region. Although ossification occurs over time, the severe coxa vara deformity persists.
- Progressive LLD can be accurately predicted using the multiplier method.1,2,10 Determining the LLD at maturity and using the Paley classification system allows the surgeon to formulate an overall strategy for deformity correction and limb lengthening.
- The number and timing of surgical procedures can be presented as a general overall plan to the parents during the initial consultation.

PATIENT HISTORY AND PHYSICAL FINDINGS

- A general history and physical examination should be performed.
- The clinician should concentrate on family history or concurrent known congenital abnormalities, which could
Chapter 28 TREATMENT OF CONGENITAL FEMORAL DEFICIENCY

Type 4: Distal Deficiency of Femur

FIG 1 • Paley classification of congenital femoral deficiency. (Copyright 2006, Sinai Hospital of Baltimore.)
indicate a genetic syndrome that could require further workup and genetic consultation.

- The facies and upper extremities are examined, looking for abnormal appearance or multiple congenital anomalies, which can indicate a genetic syndrome. In such cases, genetic consultation should be obtained.

- **Hip ROM**
  - Abduction–adduction and flexion ROM are examined in the supine position. Thomas test (hip extension) is performed to measure fixed flexion deformity of the hip. Hip internal rotation–external rotation is measured in the prone position, together with the thigh–foot angle. Muscle length tests include popliteal angle (hamstring length) and prone knee bend (rectus femoris muscle).
  - ROM is measured and contractures are identified and quantified in degrees. A popliteal angle of more than 0 degrees and prone knee bend less than supine knee bend indicate tightness of the hamstring and rectus femoris muscles, respectively.
  - Contractures need to be treated in preparation for lengthening. Lengthening of the rectus femoris and hamstring muscles is recommended for positive muscle tightness.

- **Knee ROM**
  - Flexion and extension knee ROM is measured in the supine and prone positions.
  - Greater than 10 degrees of fixed flexion deformity should be corrected during preparatory procedures. A fixed flexion deformity can be present.

- **Knee stability (anteroposterior)**
  - The Lachman test and the anterior and posterior drawer tests are performed. The clinician looks for posterior sag and rotatory instability. The amount of instability is measured:
    - Grade I: mild with endpoint
    - Grade II: moderate with endpoint
    - Grade III: moderate or severe with no endpoint
  - Anteroposterior knee instability is common.

- **Knee stability (rotatory)**
  - The rotatory stability of the knee joint is examined by internally and externally rotating the tibia on the distal femur in flexion and extension. The presence of subluxation with rotation of the tibia on the distal femur is noted.
  - External rotatory instability is a common finding that is secondary to a contracted iliotibial band, which can lead to rotatory subluxation of the knee and patellar dislocation.

- **Patellar stability**
  - The clinician should flex the knee and palpate the alignment of the patella to the notch in flexion. Tracking of the patella is assessed from 0 to 90 degrees. The clinicians should attempt to push a thumb into the intercondylar notch.
  - If the examiner’s thumb is able to palpate the intercondylar notch with the patient’s knee flexed, this denotes lateral subluxation or dislocation of the patella.
  - Patellar instability is common and can be an indication of lateral rotatory instability of the knee and contracture of the iliotibial band.

- **The clinician should look at the overall appearance of the foot and ankle.**
  - Any missing rays or positional abnormalities are noted. Ankle ROM is tested with knee flexed and extended. Inversion and eversion ROM is tested.

- The amount of dorsiflexion, plantarflexion, inversion, and eversion is recorded. Equinovalgus deformity with missing lateral rays indicates concurrent fibular hemimelia. Subtle increase in eversion ROM indicates fibular hypoplasia or a ball-and-socket ankle joint.

### IMAGING AND OTHER DIAGNOSTIC STUDIES

- During the initial evaluation of an infant with CFD, supine long anteroposterior (AP) and lateral radiographs should be obtained that include the pelvis and both lower extremities. Both lower limbs are pulled down to make sure both knees are in maximum extension (FIG 2A).
- The supine long AP view radiograph should be assessed for the overall appearance of the ossific anatomy. This radiograph should allow the physician to classify the type of CFD.
  - The lengths of both femora and both tibiae should be measured. The difference between them is the LLD, not including the foot. The clinicians should measure from the lateral acetabular edge to the midpoint of the knee joint space for the femoral lengths and from the same midpoint of the knee joint space to the end of the tibial ossific nucleus for the tibial lengths. The amount of current LLD can be used with the multiplier method to predict the overall LLD at maturity.\(^1,2,10\)
  - The acetabulum should be assessed for dysplasia using the center–edge (CE) angle (even in infants) and the acetabular index (AI).
  - The long lateral view radiograph of the lower extremity is assessed for underlying fixed flexion deformity of the knee.
  - The anterior cortical line of the distal femur should normally be colinear with the anterior cortical line of the proximal tibia. A flexion angle between these lines represents fixed flexion deformity of the knee.
  - Other imaging studies that are useful include magnetic resonance imaging (MRI) and arthrography of the hips. If the presence of a true pseudarthrosis of the proximal femur is questionable, an evaluation with MRI can be used in an attempt to visualize the presence or absence of a cartilaginous connection between the femoral head and shaft (FIG 2B,C).
  - Arthrography under general anesthesia is the gold standard to determine the presence of pseudarthrosis versus delayed ossification of the proximal femur. While the arthrogram is obtained, the lower extremity is manipulated and the proximal femur is visualized.
    - If the proximal femur and femoral head move as a unit, this denotes a cartilaginous connection in the proximal femur, and the CFD is classified as type 1b. The arthrogram is also useful to differentiate between Paley types 2a and 2b. Both 2a and 2b might have a femoral head present; the difference is whether the femoral head is fused to the acetabulum or not. If dye can be injected into a joint space, the hip can be classified as type 2a.

### DIFFERENTIAL DIAGNOSIS

- If the patient has bilateral CFD, the clinician must consider the following differential diagnoses:
  - Camptomelic syndrome
  - Femoral hypoplasia (unusual facies syndrome)
NONOPERATIVE MANAGEMENT

- Shoe lifts, orthoses, and prostheses are used for the nonoperative management of LLD. All children should receive a shoe or prosthesis with a lift when they begin to cruise the furniture. A simple shoe lift of an amount equal to 1 cm less than the LLD is used in most cases in which LLD is less than 10 cm (FIG 3A).

- It is helpful to supplement the lift with an articulated ankle–foot orthosis (AFO) for ankle support from the long lever arm of the shoe lift. If the lift is more than 10 cm, a prosthetic foot connected to an AFO is preferred both to reduce weight and improve cosmesis.

- The clinician should avoid splinting the foot in equinus because it might cause an equinus contracture.

- In children younger than 6 years, a limb-length radiograph should be obtained every 6 months to assess LLD and prescribe a new lift.

- After age 6 years, annual assessment and prescription is adequate.

- In more severe cases with hip and knee fixed flexion deformity, it might be necessary to extend the orthotic or prosthetic support above the knee (FIG 3B).

SURGICAL MANAGEMENT

- Patients with types 1a, 1b, 2a, and 2b CFD can be managed successfully with lengthening reconstruction surgery as opposed to prosthetic reconstruction surgery.

- Before undergoing lengthening reconstruction surgery, patients with certain knee and hip deformities and deficiencies should undergo preparatory procedures to prevent complications during lengthening and to reconstruct the knee and hip joints. This chapter will present the preparatory surgical procedures of the hip and knee and the external fixation method we prefer for CFD lengthening surgery.

Type 1 CFD

- Type 1 CFD is the most reconstructable.

- Before lengthening, hip stability should be determined radiographically. The best indicator is the CE angle. If the CE angle is less than 20 degrees, a Dega osteotomy should be performed before lengthening. In addition, the AI should be less than 30 degrees. If the CE angle is borderline 20 degrees but the AI is high, it is better to err on the side of caution and perform a Dega osteotomy (FIG 4).

- Coxa vara should be corrected before lengthening if the neck-shaft angle is less than 120 degrees. When coxa vara and hip dysplasia are present and when the coxa vara is severe, the superhip procedure is performed. The pelvic and femoral osteotomies should be performed 6 to 12 months before the first lengthening. The superhip procedure is a comprehensive
surgery to correct the proximal femoral and hip deformities with concurrent soft tissue releases.

- At the conclusion of a successful superhip procedure, the re-orientation of the proximal femur allows for ossification of the proximal femur (type 1b [ie, femoral neck or subtrochanteric region]). This ossification converts type 1b to type 1a and usually occurs within 2 years of the superhip procedure. Lengthening is not performed in type 1b cases until they convert to type 1a (except in special circumstances).

Type 2 and 3 CFD

- The strategies that should be used to treat types 2 and 3 CFD are complex and beyond the scope of this chapter. A summary of the strategies is provided below.

Type 2 CFD

- The presence or absence of a mobile femoral head in the acetabulum determines the treatment strategy. Although MRI and arthrography can be used to examine the femoral head for mobility, opening the hip joint capsule is the only definitive way to determine the presence or absence of a mobile femoral head.
- If the femoral head does not move in the acetabulum, it should not be joined to the femoral shaft. If the femoral head is mobile, it can be connected to the remainder of the femur by a complicated procedure in which the femoral neck is reconstructed.
- We call this procedure superhip 2, and it converts type 2a CFD to type 1a. For type 2b CFD, only the superhip soft tissue release is performed without the osteotomy. The flexion contracture of the hip is released and the fascia lata excised. Serial lengthenings with external fixation to the pelvis, femur, and tibia are performed before skeletal maturity. A pelvic support osteotomy is performed during the final lengthening at skeletal maturity.

Type 3 CFD

- Type 3a can be treated like type 2b. Patients can undergo hip release, serial lengthenings, and pelvic support osteotomy or they can be treated by prosthetic fitting options, including prosthetic reconstruction surgery (ie, Syme amputation or rotationplasty).
- Prosthetic reconstruction surgery is recommended for type 3b CFD, which includes a stiff knee joint (less than 45 degrees of motion). Although type 3a can be converted to type 2b, the treatment would consist of four or more lengthenings. Rotationplasty is recommended for type 3a because it provides a more predictable functional result than does lengthening (FIG 5).

Lengthening

- The number of lengthenings that are required for type 1 CFD is determined by the initial LLD prediction. Patients with type 1a CFD typically undergo their first lengthening at age 3 years. Patients with type 1b typically undergo lengthening closer to age 4 years. Between 5 and 8 cm can be obtained during each lengthening.
- For type 1 CFD, the femur should be lengthened by using a distal femoral osteotomy instead of a proximal femoral osteotomy.
- Distal osteotomies allow for better regenerate bone formation because they have a broader cross-sectional diameter and because the bone is not sclerotic or dysvascular, which often is seen in the proximal femur of patients with CFD. Distal osteotomies can also be used to simultaneously correct the valgus deformity of the distal femur.
- Proximal osteotomies are used to correct the external femoral torsion and proximal varus deformities. Proximal osteotomies are not used for lengthening because of poor regenerate bone formation. A proximal osteotomy can be used for deformity correction with a concurrent distal osteotomy for lengthening.
- Soft tissue releases are performed during lengthening to prevent subluxation and stiffness of the knee and hip. Soft tissue releases that were addressed during a previous superhip or superknee procedure do not need to be repeated.

Lengthening Via External Fixators

- Femoral lengthening with an external fixator can be performed with various devices.
- The essential principle of lengthening with external fixation is to stabilize the knee during lengthening while allowing for knee motion. This is accomplished by using hinges and external fixation of the tibia.
- From 1987 to 2000, only the Ilizarov apparatus was used with fixation across the knee joint with a hinge. This method
has previously been described. We did not use a monolateral external fixator because it could not articulate across the knee joint.

Since 2000 a method was developed that combined the pediatric Limb Reconstruction System (LRS) (Orthofix, Inc., McKinney, TX) with Sheffield Ring Fixation System components (Orthofix) to articulate across the knee with fixation to the tibia. Both Ilizarov and Orthofix parts are used to create this construct.

Preoperative Planning

Preoperative evaluation consists of obtaining radiographs and performing a physical examination as previously described.

The radiographs are assessed as previously described and the CFD is reclassified if progressive ossification has occurred.

During each visit before the first surgical reconstruction, LLD is recalculated to increase accuracy so that the overall strategy can be altered as needed.

Positioning

The patient undergoing the superhip procedure is positioned supine on the operating table with a bump placed under the ipsilateral sacrum to tilt the pelvis about 35 to 40 degrees. The entire lower extremity to include the groin, iliac crest, and gluteal region is prepared to the subcostal margin (FIG 6A).

The patient undergoing the initial femoral lengthening is positioned supine on the operating table with a radiopaque grid placed under the operating table pad. A small bump is placed under the ipsilateral sacrum to allow the extremity to rest in a patella-forward position. The entire lower extremity to include the groin, iliac crest, and gluteal region is prepared (FIG 6B).

Approach

The approach for the superhip and superknee procedure is the same extended lateral approach to the hip, femur, and knee as described in the following section.

The lengthening procedures are performed using percutaneous techniques.
SUPERHIP PROCEDURE

- An anterior incision is made starting two to three fingerbreadths posterior to the anterior superior iliac spine and at the level of the iliac crest. This incision gently curves to the posterolateral border of the femur along the level of the posterolateral intermuscular septum.
- A second S-shaped incision is made from the lateral side of the patellar tendon and is extended proximally in line with the intermuscular septum at the level of the knee joint. A bridge of intact skin is left between the two incisions. A recently developed distal alternative is an anterior midline incision.
- If the extremity is significantly short, these incisions become one extended approach.
- The flap of skin and the subcutaneous tissues are reflected in a full-thickness fashion off the deep fascial layer anteriorly.
- For the proximal incision, the interval between the TFL muscle and the sartorius muscle is dissected.
- For the distal incision, the fascia lata’s anterior and posterior borders are exposed at the level of the superior pole of the patella. The posterior border blends with the posterolateral intermuscular septum (TECH FIG 1A,B).
- At the TFL-sartorius interval, the fascia is split longitudinally. Care is taken to avoid injury to the lateral femoral cutaneous nerve. This is accomplished by releasing the fascia on the tensor fascia lata side of the intermuscular septum.
- This fascial incision is extended distally to join the anterior margin of the fascia lata that was previously exposed.
- The fascia lata is cut distally at the tibia and is reflected proximally if a concurrent superknee procedure with knee ligamentous reconstruction is not required. If ligamentous reconstruction is planned, the fascia lata is cut proximally and reflected distally.
- The TFL muscle is reflected proximally and posteriorly on its posterior pedicle. Its anterior vascular pedicle (ie, lateral femoral circumflex vessels) can be cauterized and cut.
- The TFL muscle is separated from the underlying gluteus medius muscle distally. If the muscles do not separate well, the interval is left alone. The surgeon must remember that any tissue that is inserting onto the greater trochanter is the gluteus medius muscle and must remain intact (TECH FIG 1C).
- The conjoint tendon of the rectus femoris, before it divides into the direct and reflected heads, is transected.
- The psoas tendon is exposed and released at the level of the pelvic brim. The surgeon must realize that the femoral nerve is much closer to both the rectus femoris and psoas tendon in patients with CFD. Therefore, the femoral nerve is identified and protected before the aforementioned releases (TECH FIG 1D).
- If the anterior fascia of the thigh and the fascia of the sartorius muscle are tight, they are released. The lateral femoral cutaneous nerve is identified and protected before releasing the fasciae.
- The femur should now be adducted, internally rotated, and flexed such that the greater trochanter is brought to the level of the center of the femoral head and the posterior border of the greater trochanter is parallel to the floor. If the proximal femur cannot be placed in this position, there is an abduction contracture of the hip joint. In these cases, the glutei muscles should be elevated off the greater trochanter along with the vastus lateralis muscle as a trigastric flap.
- The posterior border of the vastus lateralis at the intermuscular septum is identified and dissected free of the femur subperiosteally. The dissection is continued proximally along the posterior aspect of the greater trochanter. It is important to peel a thin layer of cartilage with the flap because the tendinous covering over the trochanter is thin.
- The dissection of the posterior border of the greater trochanter is continued proximally to sharply reflect the tendinous portions of the gluteus medius and minimus muscles as a continual sling (TECH FIG 1E).
- The flap of the conjoint gluteus–quadriceps tendon is sharply dissected and reflected from posterior to anterior off the trochanter. It is then reflected anteriorly off the intertrochanteric line, leaving the anterior hip capsule intact. The dissection should remain extra-capsular. The capsule should not be incised, and the pelvic trochanteric ligament running superior to the hip joint capsule should never be cut. During the release, the piriformis tendon should be identified and released, which allows the femur to rotate internally. The surgeon should avoid releasing the hip capsule from the greater trochanter because doing so can lead to hip instability, lateral subluxation, and dislocation (TECH FIG 1F).
- An alternative approach for patients with mild abductor contractures is to split the iliac crest apophysis and dissect the gluteal muscles in a subperiosteal fashion. This allows the gluteal muscles to slide distally, resolving the abductor contracture. This exposure is later used for the Dega osteotomy. At the completion of the procedure, the iliac crest is then resected by 1 cm to allow for closure of the apophysis with no tension.
- An arthrogram of the hip is obtained. The femoral head and neck are placed in a neutral orientation to the pelvis by extending and maximally adducting the hip joint.

Plate Fixation of Proximal Femur

The preferred method of fixation is the hip plate method. The preferred implant is the 130-degree pediatric cannulated blade plate (custom ordered from Smith & Nephew, Memphis, TN). If this is unavailable, the pediatric sliding hip screw (Smith & Nephew, Memphis, TN) can be used with a second screw for rotational control.

The first step is to place a guidewire from the tip of the greater trochanter to the center of the femoral head. This creates the proximal femoral joint orientation line (TECH FIG 2A).

A second guidewire is inserted in the center of the femoral neck to the center of the femoral head, at a 45-degree angle with the initial guidewire. The second guidewire is then visualized under a lateral fluoroscopic view to confirm its position in the center of the femoral head ossific nucleus (TECH FIG 2B,C). The correct
Chapter 28  TREATMENT OF CONGENITAL FEMORAL DEFICIENCY

TECHNIQUES

TECH FIG 1 • Superhip procedure. A. Incision. A point 4 to 6 cm posterior to the anterior superior iliac spine is marked on the skin, and the lateral “bump” is marked on the skin. These two points are connected with a curvilinear line that extends distally on the posterior margin of the vastus lateralis muscle belly. The second incision is a distal S incision that begins at the level of the lateral intramuscular septum on the side of the thigh and proximally at the level of the superior pole of the patella and extends to the lateral margin of the patellar tendon to the tibial tubercle. The anterior flap is dissected off the deep fascia to the midline of the thigh.

C. Reflection of fascia lata and TFL muscle. The anterior and posterior margins of the fascia lata are dissected as described, with the fascia lata being released proximally at the musculotendinous junction of the TFL muscle. The fascia lata is reflected distally to its insertion on the tubercle of Gerdy of the proximal tibia. The TFL muscle is dissected off the gluteus minimus and medius and reflected proximally.

D. Hip flexion contracture release. After the TFL muscle is reflected proximally, the dissection is continued medially under the sartorius muscle. The rectus femoris tendon is the first structure identified as it inserts on the anterior inferior iliac spine. This tendon is released, and the psoas muscle and tendon are then identified. Before release of the psoas tendon, the femoral nerve, which is adjacent to the psoas tendon, is identified and decompressed. E,F. Release of abduction and external rotation contracture. The confluent tendinous portions of the hip abductor muscles (gluteus minimus and medius muscles) and the vastus lateralis muscle are sharply dissected off the cartilaginous greater trochanter, creating a continuous musculotendinous sling. This release resolves the abduction contracture and allows access to the piriformis tendon. FL, fascia lata; m, muscle; n, nerve; RF, rectus femoris; TFL, tensor fascia lata; VL, vastus lateralis. (Copyright 2007, Sinai Hospital of Baltimore.)
orientation on the lateral fluoroscopic view is when one can see a “bullseye” created by the concentric circles of the arthrographic outline of the femoral head and femoral neck with the ossific nucleus in the center.

- The appropriate sized cannulated blade plate chisel is driven over the femoral neck guidewire to create a path for the blade plate (TECH FIG 2D). The chisel should be oriented perpendicular to the straight posterior border of the greater trochanter. The chisel is removed, and the appropriately-sized cannulated blade plate is inserted over the femoral neck guidewire (TECH FIG 2E).

- At the intertrochanteric level, two wires are inserted perpendicular and parallel to the side plate. A sagittal saw is used to remove a triangular segment of bone. The first cut is parallel to the plate, and the second cut is perpendicular to the plate. The width of the second cut is equal to the diameter of the femoral diaphysis (TECH FIG 2F).

- A second subtrochanteric osteotomy is performed by cutting obliquely from the lateral starting point of the previous parallel cut. This cut divides the femur into two segments and leaves a medial buttress of bone (TECH FIG 2F).

- The distal femoral segment is extended, abducted, and internally rotated and aligned with the plate allowing the femoral segments to overlap. The bone ends have to overlap because of the constraints of the surrounding soft tissues. The amount of overlap determines the amount of shortening of the distal segment that is required (TECH FIG 2G,H).

- A third osteotomy is performed perpendicular to the distal femoral shaft at the level of overlap (usually 1 to 2 cm distal to the second osteotomy site). The distal femoral segment is reduced to the plate and fixation is completed with three or four screws. The resected bone segment is used in the Dega osteotomy at the end of the procedure (TECH FIG 2I).

- For type 1b cases (delayed femoral neck ossification), an adjunct treatment can be performed by drilling a channel with a diameter of 3.2 to 3.8 mm into the femoral neck and packing bone morphogenetic protein (INFUSE Bone Graft, Medtronic, Inc., Memphis, TN) into the cartilaginous tunnel to induce ossification of the femoral neck (TECH FIG 2I).

Pelvic Osteotomy

- The next step is to perform the Dega osteotomy. To expose the ilium, the iliac crest apophysis is split and detached with the periosteum. The outer table of the ilium is subperiosteally dissected, and the hip abductor muscles are lifted from anterior to posterior. The posterior dissection is continued to the sciatic notch and should not cross the triradiate cartilage (TECH FIG 3A).

- The pelvic osteotomy is curved along the lateral cortex from the anterior inferior iliac spine (AIIS) to the triradiate cartilage posteriorly. At the AIIS, the osteotomy goes through both tables of the ilium. It is important to cut the apophysis and periosteum transversely at this level to allow the osteotomy to separate anteriorly. The osteotomy does not enter the sciatic notch but passes anterior and parallel to the level of the triradiate cartilage. The apex of the osteotomy should start 2 cm above the hip joint and is inclined to the triradiate cartilage medially (TECH FIG 3B).
TECH FIG 2 • (continued) (E) Cannulated 130-degree pediatric blade plate is inserted over the femoral neck guide pin to its final position. The protruding plate is used as a guide for the initial bone cuts. The plate should be parallel to the posterior trochanteric border to ensure correction of the flexion deformity. (F) Sagittal saw is used to remove a triangular segment of bone (first osteotomy). The two bone cuts are parallel and perpendicular to the plate. The width of the perpendicular cut is equal to the femoral diaphysis. The second osteotomy is started at the parallel cut and directed distally in an oblique fashion. This creates a medial buttress on the proximal femoral fragment. (G,H) Distal femoral segment is adducted, extended, internally rotated, and aligned with the side plate. The distal segment overlaps the proximal segment due to the soft tissue constraints. This determines the amount of shortening required and the position of the third osteotomy. The third osteotomy is performed perpendicular to the distal femoral diaphysis. (I) Distal femoral segment is reduced to the side plate and secured with three to four cortical screws. For type 1b cases, an adjunct treatment can be performed by drilling a channel with a diameter of 3.2 to 3.8 mm into the femoral neck and packing bone morphogenetic protein (INFUSE Bone Graft, Medtronic, Inc., Memphis, TN) into the cartilaginous tunnel. (Copyright 2009, Sinai Hospital of Baltimore.)
- The osteotomy is levered distally and laterally to cover the femoral head. The large opening wedge is maintained by inserting the resected femoral segment. The end point of correction is a horizontal sourcil (TECH FIG 3C).
- The stability of the graft is tested by attempting to pull the graft from the osteotomy site with a Kocher clamp. The graft should be fully within the lateral cortical margins of the ilium. Typically, the graft is extremely stable and no further fixation is needed.
- With the abductor sparing approach, the medial apophysis is pried off the crest. The crest is then resected using a saw until the medial and lateral apophysis can be repaired without excessive tension.
- With the trigastric flap approach there is no apophysis to repair, but the trigastric tendon has to be fixed to the cartilaginous trochanter. The hip should be slightly abducted to make sure the abductors are under tension.
- The tensor fascia lata is then sutured to the greater trochanter.
- The femur is placed in neutral abduction, and the conjoint abductor–quadriceps tendon is sutured directly into the cartilaginous greater trochanter with absorbable suture under some tension.
- The TFL is also sutured to the greater trochanter.
- The incision is closed in layers. A suction drain is used and is left in place until the draining stops (less than 10 cc per 24 hours), which can take several days. Prophylactic antibiotics are administered intravenously until the drain is removed.
- A spica cast is applied with the hip in full extension, neutral abduction, and neutral rotation. The knee is splinted in full extension. The cast is removed 6 weeks after surgery. Recently, we have been splitting the cast in surgery and allowing early ROM and bathing between splinting with the cast.

TECH FIG 3 • (A) Dega osteotomy is performed by exposing the outer table of the ilium by splitting the iliac crest apophysis and lifting the abductor muscles. (B) Osteotomy curves from the anterior inferior iliac spine to the triradiate cartilage along the lateral cortex of the ilium. The osteotomy does not enter the sciatic notch or cross the triradiate cartilage. In the coronal plane, the apex of the osteotomy starts 2 cm above the joint and is inclined toward the triradiate cartilage medially. (C) Osteotomy is levered distally to cover the femoral head, and the opening wedge is filled with the resected femoral segment graft. The end point of correction is a horizontal sourcil that is confirmed with the use of fluoroscopy. (D) The iliac crest is now resected to provide both additional bone graft for the Dega osteotomy and to relax the hip abductors to correct the preoperative abduction contracture. (E) Preoperative radiographic example of bilateral congenital femoral deficiency. (F) Postoperative radiograph obtained after superhip procedure. A Dega osteotomy is completed with horizontal sourcil. Note the complete femoral head coverage. (Copyright 2009, Sinai Hospital of Baltimore.)
SUPERKNEE PROCEDURE

Incision and Dissection

- If significant knee instability is present, a superknee procedure should be performed conjointly with the superhip procedure. The superknee procedure can address ACL and PCL insufficiency, patellar subluxation or dislocation, and maltracking. Different parts of the procedure can be used depending on the knee pathology.

- A long, S-shaped incision is made to expose the knee. The anterior and posterior margins of the fascia lata are incised longitudinally. The fascia lata is transected as proximally as possible and reflected distally until its insertion onto the tibia. (TECH FIG 4A,B). The proximal aspect of the incision is developed as described for the superhip procedure.

- The biceps femoris tendon should be Z-lengthened if knee flexion deformity is present or if the tibia is externally rotated on the femur. The peroneal nerve should first be identified as it emerges from behind the biceps femoris muscle and decompressed at the first and second tunnel of compression in the anterior and lateral compartments of the lower leg (TECH FIG 4C).

Patellar Stabilization

- The fascia lata is split into two longitudinal strips to make two ligaments. A Krackow whipstitch is used to run a nonabsorbable suture from the free end of the fascia lata toward the tubercle of Gerdy in a tubular fashion (TECH FIG 5A).

- A lateral release of the capsule leaving the synovium intact is performed in all cases.

- A Grammont procedure is performed to medially transfer the patellar tendon if patellar maltracking is significant.

- This procedure is done by releasing the patellar tendon from proximal to distal and from lateral to medial, leaving intact a long sleeve of periosteum distally. The periosteal extension of the tendon is elevated with the tendon so that the detached tendon remains tethered distally. The patella and patellar tendon are shifted medially and sutured into position with an absorbable suture (TECH FIG 5B).

- A modified Langenskiöld procedure is performed when fixed patellar subluxation or dislocation is present (see TECH FIG 4A).
description below in Alternative Step for Patellar Realignment).

- The lateral capsule is cut to, but not through, the synovium. The vastus lateralis muscle is elevated off the intermuscular septum.
- If the patella is still tethered laterally by the vastus lateralis muscle, its tendon is released from the lateral aspect of the patella and transferred centrally to the quadriceps tendon under minimal tension.
- The lateral release is extended distally to the lateral aspect of the patellar tendon. If a Grammont procedure is to be performed, the incision is extended past the tibial tuberosity along the crest of the tibia so that the proximal periosteum is elevated as described above.

**ACL Reconstruction**

- Next, a MacIntosh intra-articular or extra-articular ACL reconstruction (or both) is performed. The lateral collateral ligament (LCL) is identified. Two tunnels are made. One tunnel is placed under the LCL and does not enter the knee joint (TECH FIG 6A). The other tunnel is made subperiosteally, from anterior and proximal to posterior and distal, over the lateral intramuscular septum of the femur.
- A hole is made in the posterior knee joint capsule by inserting a curved clamp from the “over-the-top” position.

- The posterior limb of the fascia lata is passed under the LCL. An ACL reamer is used over a guidewire to create a bony tunnel in the proximal tibial epiphysis. The wire is inserted from the anteromedial aspect of the tibia and is directed to the center of the tibial epiphysis. The outer diameter of the actual graft is measured, and the hole in the epiphysis is reamed to this diameter (TECH FIG 6B). A suture passer is passed through the tibial epiphyseal tunnel and out the posterior capsule of the knee to exit laterally anterior to the septum. The fascia lata suture is pulled through the knee and the bony tunnel using the suture passer. A bioabsorbable headless screw (Arthrex, Inc., Naples, FL) is used to secure the graft to the tunnel (TECH FIG 6C). The ACL graft is tensioned and sutured with the knee reduced and in full extension to prevent creation of a fixed flexion deformity of the knee.
- If only an extra-articular ACL repair is needed, the fascia lata is looped back after passing under the LCL and the lateral intramuscular septum. The fascia lata is sutured to itself and no tunnel is made (TECH FIG 6D,E). To prevent loosening, the graft can be reinforced and retensioned after fixation by passing a nonabsorbable suture through bone at the point at which the graft loops over the intermuscular septum.
- Extra-articular or intra-articular PCL reconstruction is performed.
**Extra-articular PCL Reconstruction**  
(Reverse MacIntosh Procedure Developed by Paley)\(^8\)

- The anterior skin flap is elevated off the knee and dissected and reflected medially until the entire vastus medialis muscle can be visualized.
- The anterior limb of the fascia lata is not tubularized. It is passed first under the patellar tendon and then through a medial capsular tunnel. The graft is then passed through a subperiosteal tunnel around the adductor magnus tendon. Finally, it is sutured to itself with nonabsorbable suture (TECH FIG 7).
- This extra-articular ligament is tensioned with the knee in 90 degrees of flexion to prevent an extension contracture.
- To expose the medial side, the medial soft tissue flap is reflected to the midline.

**Intra-articular PCL Reconstruction**

- The peroneal nerve is identified, decompressed, and protected.
- The lateral head of the gastrocnemius muscle is then released from the femur. The posterior aspect of the proximal tibial epiphysis is identified to the midline.
- An anterior-to-posterior drill hole is made through the epiphysis, and the anterior limb of the fascia lata is passed from anterior to posterior, exiting near the midline posteriorly.
- Another drill hole that passes through the medial distal femoral epiphysis from anteromedial to posterolateral is made. The ligamentized fascia lata is pulled through the posterior capsule and into the medial femoral epiphyseal tunnel using its leading suture. It is fixed in place with a biotenodesis absorbable screw (Arthrex) after tensioning in flexion.

**Alternative Step for Patellar Realignment: Langenskiöld Reconstruction**

- If the patella has a fixed lateral subluxation or dislocation, a modified Langenskiöld patellar reconstruction is performed before the knee ligamentous reconstruction (intra-articular and extra-articular).
This procedure is performed through the same superknee incision and can be performed as a part of the overall reconstruction.

The retinaculum is released on both the medial and lateral aspect of the patella. This is the same incision used for the lateral release (TECH FIG 8A,B).

The incision is taken down to the synovial layer without violating the synovium. The synovium is then carefully dissected free of the undersurface of the quadriceps muscle proximally and from the patellar tendon distally.

Medially, the capsule is incised proximally in a longitudinal fashion, separating the vastus medialis muscle from the vastus intermedius muscle.

The distal medial capsule is cut transversely at the level of the joint line. The capsule is separated from the synovium as far as the medial gutter.

Once the synovial layer has been separated completely from the overlying tissues, its connection to the patella is incised circumferentially (TECH FIG 8C,D). The quadriceps and patellar tendon are left attached to the patella and the entire extensor mechanism can be shifted medially.

**TECH FIG 8 • A,B.** Initial step in the modified Langenskiöld reconstruction is to perform a medial and lateral capsulotomy. The knee joint capsule is dissected away from the synovium medially and laterally. The synovium also is dissected free from the quadriceps tendon and the patellar tendon. **C,D.** Synovium is released from the patella circumferentially, leaving the quadriceps and patellar insertions intact. **E,F.** The hole in the synovium is closed longitudinally with absorbable suture, leaving the patella with the quadriceps and patellar attachments extra-articular. The Grammont elevation and Grammont medial patellar tendon shift are then performed (see Tech Fig 5). *(continued)*
The synovium is now a free tissue layer with a patella-sized hole in the center.

- The synovial hole is sutured longitudinally with absorbable suture (TECH FIG 8E,F). The patella is left extra-articular at this point.
- The Grammont procedure is performed as described above, and the patellar tendon is shifted medially. The patellar tendon is secured with absorbable suture.
- The patella with the quadriceps muscle is now realigned medially to its new position and a marking pen is used to mark its new location on the synovium (TECH FIG 8G).

The synovium is incised longitudinally with the knee in full extension (TECH FIG 8H). The patella is inserted into this new position and sutured circumferentially to the synovium with a continuous absorbable suture (TECH FIG 8I,J).

- The medial retinacular flap is now advanced over the patella and sutured to the lateral side of the patella (TECH FIG 8K).

Once the modified Langenskiöld reconstruction is completed, the ACL and PCL knee ligamentous reconstruction, as previously described, is performed (TECH FIG 8L,M).

**TECH FIG 8 • (continued)**

G. Knee is positioned in full extension, and the new position for the patella is marked on the synovium. H. A longitudinal incision is created in the synovium. I,J. The synovium is sutured to the patella in a circumferential fashion. K. The medial capsule is advanced and sutured onto the lateral side of the patella. The lateral capsule is not repaired. L,M. If an extra-articular posterior collateral ligament (reverse MacIntosh) procedure is performed, the Langenskiöld reconstruction is completed before the ligamentous reconstruction. Fascia lata graft passes through the advanced medial capsule and is sutured onto itself. BF, biceps femoris muscle; m., muscle; RF, rectus femoris tendon; VM, vastus medialis. (Copyright 2009, Sinai Hospital of Baltimore.)
FEMORAL LENGTHENING OF TYPE 1 CFD: ORTHOFIX FIXATOR TECHNIQUE

Preparatory Surgery
- The preparatory surgery that is required consists of a Dega pelvic osteotomy for underlying hip dysplasia (CE angle less than 20 degrees or AI greater than 30 degrees), rectus femoris tendon release, and iliotibial band release at the level of the superior pole of the patella. If the popliteal angle is greater than 10 degrees, the biceps femoris tendon and medial hamstrings should be released.
- If the patient has undergone a superhip procedure, the preparatory surgery has been completed and repeat releases of the soft tissues are not necessary.
- If the preparatory surgery has not been performed and the Dega osteotomy is needed, it should be combined with excision of the fascia lata, superknee reconstruction, or both. Alternatively, the soft tissue releases can also be performed simultaneously with the lengthening procedure.

Placement of Femoral Fixator
- An arthrogram of the involved knee is obtained under fluoroscopy. In the lateral view, the femoral condyles are rotated until they superimpose each other. This is considered a “true lateral of the knee” (note that this is not the patella-forward position—actually the patella will be externally rotated approximately 10 degrees in this position).
- The center of knee rotation is identified. The center of rotation is the intersection of the posterior cortical line and the distal femoral physis line.
- A 1.8-mm Ilizarov wire is inserted into the distal femoral physis at the center of rotation and parallel to the distal femoral joint line in the frontal plane (TECH FIG 9A,B).
- The pediatric LRS is aligned with the hinge-axis wire through the most distal clamp hole. A commercially available “sandwich” clamp is used in the distal clamp, which provides a second layer of pin holes more anteriorly (TECH FIG 9C,D).
- If these are not available, two pin clamp lids can be joined by 30-mm bolts to create a sandwich clamp.
- The external fixator rail is aligned with the femur in the sagittal view and the most proximal half-pin is inserted at the level of the base of the greater trochanter (this pin should be distal to the apophysis).
- The half-pins are inserted using the cannulated drill technique: a 1.8-mm or 1.5-mm wire is first inserted into the bone and the position is checked with fluoroscopy in both the AP and lateral views.

TECH FIG 9 • A,B. Intraoperative fluoroscopic images show arthrography of the knee. The lateral view is obtained, and the posterior aspects of the femoral condyles are superimposed to create the perfect lateral view. The hinge reference wire is inserted at the intersection of the posterior femoral cortical line and the distal femoral physis. This marks the center of rotation of the knee joint. C,D. Bone model shows LRS sandwich clamp placed distally, with the most distal hole containing the hinge-axis wire. The first distal half-pin is placed on the anterior row one hole proximal to the hinge-axis pin. E. Example of pediatric Orthofix rail with a three-hole cube placed on the distal half-pins to allow a third half-pin to be inserted into the distal fragment. F. Radiograph shows acute valgus correction performed at the osteotomy site for lengthening. (Copyright 2006, Sinai Hospital of Baltimore.)
If the wire is in the center of the bone, a cannulated drill is used to overdrill the wire. The half-pin is then inserted in a perfect position.

- Half-pins placed in the anterior half of the femoral diaphysis can result in a fracture either during the lengthening process or after frame removal.
- The most distal half-pin is placed one hole proximal and anterior to the knee axis reference wire.
- At this point, the position of the hinge axis is a fixed point to the initial distal half-pin. The reference axis wire is removed.
- An LRS without a sandwich clamp is now placed on the two half-pins. The additional half-pins are placed proximal and distal. Three half-pins should be placed in each segment.
- If concurrent distal valgus deformity is being corrected, a swivel clamp should be used at the proximal clamp site when placing the first two half-pins.
- When using the pediatric LRS, the standard clamp offers only three half-pin sites and one site is occupied by the knee axis dummy pin. Therefore, a three-hole Ilizarov cube should be connected to the two half-pins that occupy the pediatric Orthofix clamp and a third half-pin placed through the cube more proximal (TECH FIG 9E).
- After all half-pins are placed, the template LRS with swivel clamp is removed and a distal femoral osteotomy is performed using the multiple drill hole technique.
- The distal femoral valgus deformity is acutely corrected, and the LRS with sandwich clamp attachments is placed on the half-pins, stabilizing the correction (TECH FIG 9F).

Placement of Tibial Fixator

- The distal pins should be in the upper deck of the double-decker sandwich clamp.
- The only pin in the lower deck of the sandwich clamp is a dummy pin (i.e., partial pin that is captured by the clamp and protrudes away from the patient but does not enter the patient’s limb) in the distal lower hole.
- This dummy pin is the hinge-axis pin.
- A Sheffield clamp (Orthofix) is applied to the hinge-axis pin. Conical washers are placed medial and lateral to the Sheffield clamp to reduce friction. A single-hole Ilizarov cube and set screw are placed laterally.
- The hinge-axis pin and Sheffield clamp have now created a mechanical hinge (TECH FIG 10A,B).
- The Sheffield clamp is temporarily tightened and positioned parallel to the LRS rail. A one-third Sheffield arch is then attached to the clamp and arched medially to be anterior to the tibia. The arch should be perpendicular to the tibia in the sagittal plane (TECH FIG 10C–E).
- A single-hole ilizarov cube is placed on the Sheffield arch, and an AP half-pin is placed in the proximal tibia. As the first pin is being secured to the Sheffield arch, the knee must be in full extension and reduced.

Testing and Completion of the External Fixator Construct

- After the first half-pin is inserted into the tibia, the Sheffield clamp is loosened and the hinge tested with gentle ROM of the knee.
If the motion is smooth, a drop-leg test is performed.
- The drop-leg test consists of lifting the lower extremity off the bed and fully extending the knee. The thigh is supported and the lower leg dropped.
- If the knee flexes with no catching or friction, two additional half-pins are placed in the tibia.
- If there is friction during the drop-leg test, the hinge and knee rotation axis needs to be examined and adjusted. Usually, the dummy axis pin can be slightly bent and the hinge axis reoriented to the knee rotational axis. After the axis pin adjustment, the drop-leg test is repeated until knee ROM is smooth, with no friction (TECH FIG 11A,B).

PEARLS AND PITFALLS

Superhip—initial dissection
- Rectus femoris and iliopsoas tendons are located closer to the femoral nerve than expected. The surgeon should first identify the femoral nerve before performing any releases or tenotomies.

Superknee—knee flexion contracture
- Knee flexion contracture should be released with biceps femoris lengthening and posterior capsular release. A concurrent ligamentous reconstruction should not be performed because of postoperative stiffness of the knee joint.

Femoral lengthening
- Positioning the hinge-axis wire is the crucial step when applying the external fixator. Great care should be taken to ensure precise placement of the wire at the center of rotation of the knee (intersection of the posterior femoral cortical line and the distal femoral physis). This must be performed after an arthrogram of the knee is obtained, which allows exact visualization of the overlapped posterior femoral condyles in the lateral fluoroscopic view.

External fixator removal
- At the time of external fixator removal, a Rush pin should be placed prophylactically as described below. Activities, to include physical therapy, should be modified for 4 weeks after removal. A removable long-leg cast should be applied to maintain extension and to protect the tibia.

Femoral lengthening
- If the initial distal femoral half-pin is positioned too far anterior when placed through the sandwich clamp, the initial hinge-axis pin is too far anterior. The surgeon should carefully examine the hinge-axis wire and ensure that it is at the level of the posterior femoral cortical line.

Postoperative therapy and preservation of knee motion
- Knee flexion should be maintained at greater than 45 degrees. If knee flexion is 40 degrees or less, lengthening should be slowed or discontinued and knee rehabilitation increased.
POSTOPERATIVE CARE

- Patients who have undergone the superhip or superknee procedures are placed into a 1-1/2 hip spica cast.
- The involved limb is placed in neutral abduction, neutral rotation, and 0 degrees of extension. The knee is held in full extension, and the foot is included.
- The cast is removed at 6 weeks, and gentle ROM of all joints is performed as well as weight bearing as tolerated.
- Patients undergoing femoral lengthening require close follow-up and intensive rehabilitation. Patients are usually discharged on postoperative day 3 or 4.
- The lengthening begins on day 5 or 7 at a rate of 0.75 to 1.0 mm per day.
- The patient is assessed every 2 weeks in the outpatient clinic with radiographic and clinical examinations.
- Pin-site problems, nerve function, hip and knee ROM, and knee subluxation are assessed.
- The joint location, limb alignment, regenerate bone quality, and length gained are assessed radiographically.
- The rate of distraction is adjusted according to regenerate bone quality and joint ROM.
- Physical therapy is begun on postoperative day 1. During the distraction phase, physical therapy is continued daily, with formal therapy occurring 5 days per week.
- The formal therapy consists of one or two sessions with a therapist each day, with 1 hour of land therapy and 1 hour of hydrotherapy.
- The patient also undergoes two physical therapy sessions at home each day with the parents.
- During therapy, the patient should perform exercises that obtain knee flexion and maintain knee extension.
- Knee flexion should be maintained at greater than 45 degrees but not more than 90 degrees.
- If knee flexion is 40 degrees or less, lengthening should be discontinued or slowed and knee rehabilitation should be increased.
- If there is no improvement, lengthening is discontinued.
- During the distraction phase, passive exercises are most important; during the consolidation phase, passive plus active exercises are important. Hip abduction and extension are two important hip exercises.
- During the consolidation phase, the formal therapy can be reduced to three sessions per week if the patient is doing well. Weight bearing is allowed as tolerated.
- The frame can be removed from the femur and tibia after the regenerate bone has healed.
- A prophylactic Rush pin (Zimmer, Inc., Warsaw, IN) is placed in the femur at the time of external fixation removal (FIG 7). Application of the Rush pin prevents refracture after lengthening.
- The frame is removed under general anesthesia, and radiographs in the AP and lateral views are obtained.
- At this point, the pin sites are cleaned, prepared, and then isolated with Tegaderm dressings (3M Healthcare Ltd, St. Paul, MN). The entire lower extremity to include the hip, iliac crest, and gluteal region is prepared and draped.
- A 1.8-mm Ilizarov wire is inserted into the tip of the greater trochanter and driven into the center of the proximal femur. An intraoperative lateral view radiograph after external fixation removal is used to place the starting point on the greater trochanter. The 1.8-mm wire is drilled or tapped into the femur and then overdrilled with a cannulated 3.2-mm or 4.8-mm drill to create the starting hole for the prophylactic Rush pin insertion, depending on whether a 3.1-mm (1/8 inch) or 4.6-mm (3/16 inch) Rush pin is used.
- If needed, the femur is then sequentially reamed using T-handled hand reamers (ie, Foresight nail reamers [Smith & Nephew]) until the desired pin diameter is obtained. The hand reamer should be slightly bent at the tip to allow for careful guidance down the canal under fluoroscopic control.
- After the reaming is complete, the Rush pin is inserted and should reach just above the distal femoral physis. Its tip might need to be slightly bent to navigate the curves of the femur.
- The small proximal incision is closed, and the pin sites are dressed. The pin sites are not manipulated or released to decrease the risk of concurrent infection.
- Antibiotics are administered intravenously during the procedure, and oral antibiotics are used for 7 days postoperatively.

FIG 7 • A. AP view radiograph of right femur of a patient with Paley type 1a congenital femoral deficiency after initial lengthening of 8 cm. B. Postoperative AP view radiograph of femur after external fixation removal with insertion of Rush pin to protect the newly consolidated regenerate bone. C. Longstanding lateral view radiograph shows the inserted Rush pin after external fixation removal. (Copyright 2007, Sinai Hospital of Baltimore.)
If a significantly problematic pin site or pin-site infection is present at the time of removal, the prophylactic intramedullary rod placement is delayed for 2 weeks and the affected limb is placed into a hip spica cast.

Physical therapy is discontinued for 1 month to avoid fracture through the regenerate bone or a pin hole.

Physical therapy is restarted 1 month after frame removal and Rush pin application. With the Rush pin in place, no cast or brace is needed. The patient is allowed partial weight bearing.

OUTCOMES

Saghieh and associates\textsuperscript{12} studied our first 79 consecutive patients with Paley type 1 CFD. The patients underwent 99 femoral lengthenings between January 1988 and December 2000. Medical charts and radiographs were retrospectively reviewed. Fifty-nine patients (73 lengthenings) had Paley type 1a and 20 patients (26 lengthenings) had Paley type 1b CFD. Forty-six (58\%) were female and 33 (42\%) were male patients. The mean patient age was 12.3 years (age range, 1.5 to 62.3 years). The lengthenings were divided into three age groups: toddler (younger than 6 years), juvenile (between 6 years and skeletal maturity), and adult (skeletally mature). Because 19 patients each underwent more than one lengthening (18 underwent two lengthenings, and 1 underwent three lengthenings), each lengthening was evaluated independently as a separate lengthening and studied for its own results and complications.

- Distraction gap, percent of femur lengthened, external fixation time index, degree of preservation of knee motion, result score, and complications were compared among the groups. The complications and ROM data were routinely recorded, and the data were obtained from a review of the charts. Radiographic measurements were obtained from preoperative lower limb alignment AP view radiographs (tele-oroentgenograms), compensating for magnification, and from lateral view radiographs of the femur and tibia. The CE angle and neck–shaft angle also were measured, preferably by using an AP view radiograph of the pelvis. The average follow-up from the time of removal of the external fixator was 69 months (range, 19 to 132 months).

- The average discrepancy in femoral length was 9.1 cm (range, 1.2 to 22.1 cm) preoperatively and 4.1 cm (range, 14.7 to 2.3 cm) postoperatively. The mean distraction gap was 5.8 cm (range, 2.4 to 12.0 cm). The average duration of treatment with external fixation was 5.9 months (range, 2 to 15.9 months) with an external fixation time index of 1.07 months/cm (range, 0.49 to 2.38 months/cm). The result score was excellent in 61 (61.6\%) lengthenings, good in 29 (29.3\%), fair in 7 (7.1\%), and poor in 2 (2\%).

- Excellent and good results were achieved in 91\% of patients. No significant differences in most of the studied parameters, including result score, were observed among the different groups. The two younger groups experienced a higher incidence of fracture (no prophylactic rodding was used in this group). The adult group experienced a higher incidence of delayed union and joint stiffness. However, the overall complication rates were similar among the three groups. We prefer to begin lengthening at an early age so that additional needed lengthenings can be spaced in time.

- Currently, we are reviewing our experience since 2000. Our outcome study includes more than 250 patients with CFD who have undergone more than 350 lengthening procedures.

COMPlications

- Flexion contracture of the knee
- A significant knee flexion contracture places the knee at risk for posterior subluxation.
- One of the primary goals of physical therapy is to maintain knee extension and to continue to obtain knee flexion. Both the surgeon and therapist need to closely monitor the patient’s ROM and must be in regular communication if difficulties arise.
- To prevent fixed flexion deformity, a knee extension bar is used every night and part-time during the day. If the patient experiences a loss of motion, therapy must be increased and the patient assessed immediately.
- Acute pin-site infections can lead to increased pain and decreased motion and should be immediately treated with oral or intravenous antibiotics.
- If significant soft tissue tightness is present in the quadriceps muscle, the distraction rate should be decreased. However, decreasing the distraction rate should be followed closely with radiographs to prevent premature consolidation. If Botox was not used at the index procedure, the surgeon should consider injecting the quadriceps muscle with 10 units of Botox solution per kilogram of body weight. We perform the Botox injection under anesthesia or sedation for the younger patient.

- Adduction and flexion contractures of the hip

- Hip adduction contractures place the hip joint at risk for subluxation and dislocation during the lengthening process. Hip adduction should be assessed at the time of the lengthening surgery. If a contracture is present, an adductor tenotomy should be performed.

- Hip ROM and stretching is addressed by the therapist on a daily basis. If a contracture is a concern initially, an abduction pillow is used at night. If the patient has subluxated or dislocated the hip in a previous procedure, the external fixator should be extended above the hip with a hinge device similar to that used for the knee. Hip flexion contracture might occur when the patient is positioned in a wheelchair for prolonged periods of time.

- The patient should not only stretch during the therapy sessions, but also should be placed in a prone position on a daily basis. Occasionally, a repeat rectus femoris tendon release along with a release of the anterior thigh fascia is performed at the time of external fixation removal. Iliopsoas contracture does not occur during the lengthening because the distraction site is distal to the psoas insertion.

- Nerve injury

- Nerve injury is unusual with femoral lengthening. Complaints of pain in the foot are usually referred pain from nerve entrapment. Quantitative sensory testing is the best method to identify early nerve entrapment.\textsuperscript{7} The nerve problem can be treated by slowing the distraction or nerve decompression. The peroneal nerve should be decompressed at the neck of the fibula if symptoms continue or pressure-specified sensory device testing is positive.\textsuperscript{9} Premature consolidation

- Premature consolidation usually occurs during the first 2 cm of distraction and is rare after 4 cm of distraction. In a young child, the latency period should not be more than 7 days.
■ Increasing pain with distraction or difficulty while turning the distracting unit are signs of possible preconsolidation. Radiographs should be obtained to assess the regenerate bone. If the fibrous interzone disappears, the turning rate should be increased (ie, five quarter-turns per day) and additional radiographs obtained within 1 week.
■ If one of the cortices has bridged with narrow bone, continued distraction at an increased rate can be performed.
■ The physician must warn the parents that the patient may experience or hear an audible “pop” during distraction. This will be followed by a mild to moderate increase in pain. However, the distraction will become easier and surgery can be avoided.
■ If the regenerate site is consolidated with abundant bone, the pins might bend or become deformed. This type of preconsolidation is addressed with a repeat osteotomy 1 to 2 cm proximal to the original site. The surgeon should not attempt to repeat an osteotomy at the same regenerate site because the patient will have increased bleeding and poor regenerate bone formation. If the fibrous interzone is greater than 5 mm, lengthening should be slowed (ie, two or three turns per day).
■ Regenerate bone failure
  ■ Partial defects in the bone are not uncommon on the lateral cortex. Sequential radiographs obtained during the distraction phase must be closely followed for increasing fibrous interzone distance and poor regenerate bone formation.
  ■ Regenerate bone failure is prevented by slowing the distraction rate when signs of poor regenerate formation are present. During the consolidation phase, a partial defect can be treated with dynamization to increase healing of the regenerate bone.
  ■ If the defect persists and encompasses less than 25% of the bone diameter, a rigid intramedullary rod placed at the time of removal will allow for ossification during a prolonged time period (6 to 12 months).
  ■ If the regenerate bone failure is more severe, open autogenous bone grafting should be performed after first excising the interposing fibrous tissue.

REFERENCES
DEFINITION
- Congenital dislocation of the knee (CDK) is a rare deformity that presents at birth as recurvatum.
- The incidence of CDK is estimated at 1 per 100,000 live births, which is approximately 1% of the incidence of congenital dislocation of the hip.7
- It may be an isolated entity or occur with associated musculoskeletal anomalies such as dislocated hips, clubfoot, and congenital vertical talus. It can also occur with myelodysplasia, Larsen syndrome, and arthrogryposis.
- It varies in severity and has been classified as simple hyperextension, subluxation, and anterior dislocation of the tibia on the femur (FIG 1).3

ANATOMY
- The fundamental pathologic feature in CDK involves the quadriceps muscle. The amount of quadriceps muscle is small, and the muscle as well as the lateral retinaculum adheres to the femur.
- The quadriceps femoris tendon is shortened and fibrosed, which is thought to be secondary to the dislocation rather than its cause.3
- The patella is often laterally displaced.
- There is hypoplasia of the suprapatellar pouch.
- The hamstrings are often deficient, subluxed anteriorly, or both.
- The anterior knee articular capsule is tight.
- The menisci are usually present and normal.
- The pathology in the cruciate ligaments is variable, from absence to elongated.5

PATHOGENESIS
- The exact cause of CDK remains unknown.
- A genetic etiology is supported by the presence of familial occurrence in some cases as well as the association of CDK with developmental hip dysplasia, idiopathic clubfoot, and congenital vertical talus, all three of which have a known or presumed genetic basis.1,11
- Simple hyperextension of the knee in newborns may be caused by aberrations in intrauterine positions, such as frank breech presentation, which slowly stretches the hamstrings and posterior knee soft tissues.7 Chronic knee hyperextension results in anterior subluxation of the hamstrings, allowing them to function as knee extensors.
- Severe CDK often occurs in association with disorders with muscle imbalance, such as myelodysplasia, arthrogryposis, Larsen syndrome, Ehlers-Danlos syndrome, Streeter syndrome, and oligohydramnios.3,11

NATURAL HISTORY
- The natural history of CDK depends on the severity of the disorder on presentation. Simple hyperextension of the knee tends to resolve spontaneously or with splinting.2,6
- In cases of subluxation and dislocation, spontaneous resolution is not common, and most patients require surgical correction.
- Left untreated, these patients have great difficulty with ambulation owing to the inability to flex the knees. These patients often have associated neuromuscular or genetic syndromes.3

PATIENT HISTORY AND PHYSICAL FINDINGS
- The physical findings of CDK are readily apparent at birth but of variable severity (FIG 2).
- The knee is hyperextended, in severe cases to such a degree that the foot rests against the baby’s face.
- In cases of simple hyperextension, the knee can be passively brought into flexion.
- In the more common scenario of subluxation, passive flexion is limited but improves with splinting, casting, or both.
Nonoperative treatment consists of serial manipulations and long-leg plaster castings.2,6,10

With the patient relaxed with a bottle of milk, gentle traction is applied to the tibia to stretch the contracted quadriceps muscle. After several minutes of stretching, a long-leg plaster cast is applied from the toes to the top of the thigh. The cast is applied in one section and is carefully molded to maintain the position achieved with stretching and to avoid skin sores.

The casts are changed on a weekly basis in the clinic. Once the tibia reaches the distal femur with traction, flexion of the knee is begun.

In cases of simple hyperextension, flexion of the knee can often be started quite early (FIG 4).

In cases of subluxation and complete dislocation of the knee, however, flexion of the knee often cannot be started for several weeks until the quadriceps muscle is adequately stretched.

It is very important to obtain a lateral radiograph of the knee once knee flexion reaches 45 degrees and again if 90 degrees of flexion is reached during serial casting. It is possible to create an iatrogenic physeal separation of the distal femur or to deform the proximal tibia plastically.

Closed treatment should be stopped if anatomic reduction of the tibia cannot be confirmed.

If 90 degrees of flexion is obtained and a normal restoration of the femoral–tibial articulation is demonstrated on a lateral radiograph, it is unlikely that any surgical intervention will be necessary.

Historically, nonoperative treatment has been successful in treating simple hyperextension of the knee and some cases of subluxation. Most patients with complete knee dislocation have an extensive surgical release operation after a failed attempt at casting.

**SURGICAL MANAGEMENT**

**Preoperative Planning**

If serial casting fails to obtain a reduction of the anteriorly dislocated tibia on the end of the femur, which is verified on a lateral radiograph of the knee, surgical management should be considered.
Timing of the surgical correction depends on the particular technique that the surgeon chooses, but usually ranges from 1 month of age to 2 years.

**Positioning**
- The patient is positioned supine on a radiolucent table. No tourniquet is used as this interferes with the location of the surgical incision.
- The entire leg is prepared into the field from the hip to the tip of the toes to allow easy manipulation of the knee (FIG 5).

**Approach**
- The approach depends on the surgeon’s preference but varies from minimally invasive approaches to extensile approaches with quadriceps mechanism reconstruction.

---

**PERCUTANEOUS QUADRICEPS RECESSION**

- This procedure is ideally performed at 1 to 2 months of age and is described by Roy and coworkers.\(^1\)
- An assistant holds the affected leg and attempts to flex the knee.
- A small stab incision is made one to two patellar lengths superior to the patella in the midline of the thigh, and the fascia overlying the rectus femoris is released (TECH FIG 1).
- Medial and lateral stab incisions are then made at the superior border of the patella to release the medial and lateral quadriceps tendon and retinaculum.

- After the release is performed, the knee is flexed to 90 degrees.
- Sterile dressings are applied, followed by a long-leg plaster cast with the knee flexed at 90 degrees or greater.
- The cast is worn for 4 to 6 weeks.
- After cast removal the patient is placed in a Pavlik harness to maintain knee flexion for an additional 4 to 6 weeks.

---

**MINI-OPEN QUADRICEPS TENOTOMY**

- This approach is ideally performed between 1 and 6 months of age and has been described by Dobbs and associates (TECH FIG 2).\(^4\)
- A 2-cm vertical midline incision is made just above the superior pole of the patella.
- Dissection is carried down to the patella and the quadriceps tendon.

- The quadriceps tendon is carefully isolated with blunt dissection using a hemostat.
- The quadriceps tendon is transected completely about 1 cm proximal to its insertion on the superior pole of the patella.
- The knee is then gently flexed until at least 90 degrees of flexion is obtained.
If 90 degrees of flexion cannot be obtained after the quadriceps tenotomy, the anterior knee capsule is released as well as the lateral retinaculum until 90 degrees of flexion is obtained.

An intraoperative lateral knee radiograph is obtained to ensure anatomic reduction of the tibia on the distal femur.

After wound closure, a sterile dressing is applied, followed by a long-leg plaster cast with the knee in 90 degrees of flexion.

**EXTENSILE RECONSTRUCTION OF CONGENITAL KNEE DISLOCATION**

- This approach is usually performed between 6 months and 1 year of age.
- A midline longitudinal incision or serpentine incision can be used. The midline incision extends from the tibial tubercle to the middle of the thigh; the serpentine incision extends from the tibial tubercle to the proximal thigh.
- The serpentine incision may facilitate wound closure and result in fewer wound-healing problems than the straight incision.
- The patella, the quadriceps muscle and tendon, the patellar tendon, and the lateral retinaculum are all carefully exposed.
TECH FIG 3 • V-to-Y quadriceps advancement. A. The quadriceps tendon is exposed proximal to the patella, and most of the medial and lateral fibers are detached from the tendon. The medial and lateral retinaculum is divided to the collateral ligaments. The iliotibial band is divided if the tibia is in valgus and externally rotated. B. The posterior borders of the lateralis and the medialis are divided sharply and the flap of muscle created is dissected free of underlying attachments to the femur. This will permit the tibia and collateral ligaments to slide posteriorly and allow sufficient mobilization of the quadriceps. C. With the knee flexed at about 40 degrees, the medialis and lateralis are reattached to the quadriceps tendon, creating the V-to-Y advancement and repair. The retinaculum is not closed.

PEARLS AND PITFALLS

Indications
- A complete history and physical examination should be performed.
- Associated diagnoses must be recognized as this can alter the prognosis and treatment strategy.

Nonoperative treatment
- Care must be taken during manipulation and casting not to create iatrogenic fractures in the distal femur or proximal tibia.
- Use of radiographs can confirm anatomic reduction of the tibia on the distal femur.

Extensile surgical approach
- Reapproximation of the quadriceps mechanism must be done in 30 to 40 degrees of flexion. Flexing the knee less than 30 degrees often results in recurrent subluxation, and flexion greater than 40 degrees is too much to permit reconstruction of the quadriceps tendon.

Postoperative management
- No matter what treatment method is used to correct the deformity, splinting and range-of-motion exercises are essential to maintain flexion and minimize loss of extension. A knee flexion contracture can be more debilitating than a lack of full flexion.

Management of associated musculoskeletal problems
- Associated clubfoot deformity can be treated at the same time as the CKD by incorporating the foot into the long-leg cast using the Ponseti method.
- Management of associated hip dislocation should be done later as a staged procedure.
POSTOPERATIVE CARE

- A lateral radiograph of the knee is essential to ensure anatomic reduction of the tibia on the distal femur.
- Casting is required after each treatment method. The degree of knee flexion in the cast and the duration of casting vary with technique.
  - Percutaneous quadriceps resection
    - A long-leg plaster cast with the knee flexed at least 90 degrees is applied at the end of the procedure and worn for 4 to 6 weeks.
    - After cast removal, the patient is placed in a Pavlik harness to maintain knee flexion for an additional 4 to 6 weeks.
  - Mini-open quadriceps tenotomy
    - The initial long-leg plaster cast with the knee in 90 degrees of flexion is changed in the operating room at 3 weeks postoperatively to assess knee range of motion.
    - Another long-leg cast is applied with the knee in 70 degrees of flexion for 2 weeks. This cast is removed in the clinic and formal physical therapy is begun on an outpatient basis to maintain knee flexion and extension. Splints are also used for 4 to 6 weeks, alternating between a flexed and an extended position at the knee.
  - Extensile reconstruction: spica cast with the knee in about 45 degrees of flexion
    - Once casting is complete, close follow-up is mandatory to ensure maintenance of knee motion.
    - Splinting is also important after each treatment method to maintain maximal flexion and minimize loss of knee extension.
    - Physical therapy is also an essential part of postoperative rehabilitation and is done on an outpatient basis several times a week for up to 3 months.

OUTCOMES

- Patients with a hyperextension deformity that requires only serial manipulation and castings do very well long term both clinically and radiographically.2,5,8,10
- Roy and colleagues11 report good short-term results using the percutaneous quadriceps tenotomy, but there are no long-term data with this technique. This technique was successful only in patients without associated syndromes or neuromuscular deformities.
- Dobbs and coworkers4 report good short-term results using the mini-open quadriceps tenotomy in patients with isolated CDK as well as in some children with associated genetic and neuromuscular conditions. No long-term follow-up is available for this technique.
- Patients with severe dislocation who have undergone an extensive open procedure, but do not have any other associated musculoskeletal problem, generally do well long term if knee flexion is 80 degrees or greater.
- Children with associated neuromuscular disorders or genetic syndromes do not do as well long term.
- Children with bilateral deformities do not do as well as those with unilateral deformity.
- Early correction has a more satisfactory result than late repair.4,7,11

COMPlications

- Wound-healing problems have been reported with extensile approaches.
- Loss of flexion initially gained at surgery can be a late complication.
- Development of a flexion contracture can occur postoperatively and compromise long-term outcome.
- Iatrogenic fractures of the distal femur, proximal tibia, or both can occur with casting and manipulation.

REFERENCES

DEFINITION
■ Blount’s disease, also known as idiopathic tibia vara and osteochondritis deformans tibiae, is characterized by abnormal growth of the proximal tibia physis with progressive varus deformity.
■ Blount’s disease is classified into three types based on age of clinical onset: infantile (0–3 years); juvenile (4–10 years); and adolescent (11 years and older).
■ Infantile tibia vara is most prevalent in African-American females and is associated with obesity, internal tibial torsion, and leg-length discrepancy. Radiographs reveal a prominent medial metaphyseal beak, and the origin of the varus deformity is in the proximal tibia only. About 80% of cases are bilateral, and the potential for deformity is the greatest in this group.
■ Adolescent tibia vara is most prevalent in African American males with marked obesity, minimal internal tibial torsion, mild medial collateral ligament laxity, and mild leg-length discrepancy. The site of the deformity is in the proximal tibia and sometimes in the distal femur as well. About 50% of cases are bilateral, and pain rather than deformity is more commonly the presenting complaint.

ANATOMY
■ When evaluating patients with Blount’s disease, the normal development of the tibiofemoral angle in children must be considered.
■ The normal tibiofemoral angle in newborns is approximately 15 degrees varus. It decreases with growth, so that the tibiofemoral angle approaches 0 degrees around 18 months of age.
■ The tibiofemoral angle progresses to maximum valgus around 3 years of age and then decreases until adult physiologic valgus is achieved between 7 years of age and skeletal maturity.
■ One standard deviation of the anatomic tibiofemoral angle throughout growth is approximately 8 degrees.

PATHOGENESIS
■ Blount’s disease is likely due to a combination of genetic factors and a cycle of increased stress across the medial physis, which leads to decreased medial endochondral ossification, further varus deformity, and, subsequently, further medial physeal stress. The medial physeal stress is aggravated by obesity and progressive genu varum.
■ Histopathologic studies of infantile and late-onset tibia vara are similar to those of patients with slipped capital femoral epiphysis. Findings include fissuring and clefts in the physis, fibrovascular and cartilaginous repair at the physeal-metaphyseal junction, foci of necrotic cartilage, and marked disorganization of the medial degenerative physeal zone.

These findings are consistent with an arrest of the normal endochondral growth mechanism.

NATURAL HISTORY
■ A varus alignment of the lower extremity places excess stress on the medial compartment of the knee. This stress places the knee at increased risk for arthritis.
■ The goal of intervention is to restore the normal anatomic orientation of the knee and ankle joints and to restore the normal mechanical axis of the leg.

PATIENT HISTORY AND PHYSICAL FINDINGS
■ The chief complaint in infantile tibia vara usually is deformity. In late-onset tibia vara, in contrast, knee pain is the primary complaint. The characteristics of the pain should be elicited.
■ Patients may exhibit a limp, with or without a leg-length discrepancy. Observe the patient’s gaiting, noting a limp or lateral thrust.
■ The mechanical axis of the lower leg is in varus. Genu recurvatum and internal tibial torsion may be present as well.
■ Inspect the sagittal profile for the presence of genu recurvatum; if present, it may be necessary to address it at the time of surgery.
■ The Q angle provides a clinical estimate of the anatomic tibiofemoral angle.
■ Range of motion and collateral ligament laxity also should be assessed.

IMAGING AND OTHER DIAGNOSTIC STUDIES
■ AP long-leg radiographs (which include the hips, knees, and ankles) should be obtained. The patella (not the foot) must be pointing forward.

FIG 1 • Orthoradiograph of patient with adolescent Blount’s disease.
Infantile Blount’s disease has several characteristic radiographic findings.
- To help differentiate infantile Blount’s disease from physiologic varus, the metaphyseal-diaphyseal angle is drawn. A metaphyseal-diaphyseal angle less than 10 degrees is consistent with physiologic varus, whereas an angle of more than 16 degrees is consistent with infantile Blount’s disease.
- Acute angulation of the medial proximal tibia, medial beaking, fragmentation of the medial metaphysis, progressive varus, and unilateral involvement are consistent with infantile Blount’s disease.
- Care must be taken that the radiographs are taken with the patella forward.
- If tibial torsion is present, the feet must cross medially so that the patella is forward. The medial and lateral flares of the distal femurs will be equal if the patella is forward.
- The proximal tibia is examined to determine the Langenskiöld stage.
  - Stage I: Age under 3 years. Medial and distal beaking of metaphysis with irregularity of entire metaphysis
  - Stage II: Age 2.5 to 4 years. Sharp anteromedial depression in ossification line of wedge-shaped medial metaphysis
  - Stage III: Age 4 to 6 years. Deepening of metaphyseal beak
  - Stage IV: Age 5 to 10 years. Enlargement of epiphysis
  - Stage V: Age 9 to 11 years. Cleft in epiphysis, appearance of double epiphysis
  - Stage VI: Age 10 to 13 years. Closure of medial proximal tibial physis
- Late-onset Blount’s disease is characterized by less obvious changes in the proximal tibia.
  - These changes include wedging of the medial portion of the epiphysis, a mild postero-medial articular depression, a serpinginous curved physis of variable width, and mild or no fragmentation of the proximal medial metaphysis.
- Radiographic analysis for deformity has been well described by Paley et al.4
  - The magnitude of the overall lower extremity malalignment can be determined by the anatomic tibiofemoral angle or the mechanical axis deviation. The anatomic tibiofemoral angle is the angle between the midshaft lines of the femur and the tibia. The mechanical axis deviation is the distance from the center of the knee to the mechanical axis line of the leg.
  - Analysis of the frontal plane deformity begins with the malalignment test.
    - The mechanical axis line is drawn from the center of the hip to the midpoint of the ankle plafond.
    - To identify whether the source of the deformity is the femur, the tibia, or both, joint orientation angles are measured.
    - The mechanical lateral distal femoral angle (mLDFA, normal value 85 to 90 degrees) and medial proximal tibial angles (mPTA, normal value 85 to 90 degrees) are measured to determine which is/are abnormal.
    - The joint line convergence angle is measured to determine whether the joint line is an additional source of deformity.
    - If the midpoints of the femur and tibia are over 3 mm apart, then frontal plane subluxation is a source of deformity as well.
- Finally, the joint lines are inspected for intra-articular sources of deformity.
- The malalignment test is applied to the ankle and hip to determine whether these joints are oriented normally to the mechanical axis line.
- Abnormal joint orientation angles indicate which joints are contributing to the deformity.
- Sagittal plane radiographs are obtained and analyzed as appropriate.
- Leg lengths are measured in order to identify a leg-length discrepancy.
- The location of the deformity point, or center of rotation of angulation (CORA), is identified during preoperative planning.

DIFFERENTIAL DIAGNOSIS
- Physiologic varus
- Pathologic causes
  - Blount’s disease
  - Rickets
  - Skeletal dysplasias
  - Focal fibrocartilaginous dysplasia
  - Renal osteodystrophy
  - Osteogenesis imperfecta

NONOPERATIVE MANAGEMENT
- Nonoperative treatment with bracing may be indicated in patients with infantile Blount’s disease.
- Bracing should be considered for varus deformity greater than 15 degrees in children over 2 years of age with Langenskiöld stage I or II Blount’s disease.
- Bracing usually is not helpful in obese African-American girls over the age of 3 years.
- Nonoperative treatment with bracing is not successful in adolescent Blount’s disease.

SURGICAL MANAGEMENT
- The surgical treatment of infantile Blount’s disease is distinct from that for adolescent Blount’s disease.
- In patients with infantile Blount’s disease, the proximal tibial physis has several years of growth remaining. A proximal tibial osteotomy should be performed with the goal of correcting the anatomic tibiofemoral angle to within 5 degrees of neutral. In addition to the osteotomy, medial proximal tibial physis should be performed with the goal of improving the alignment of the physis and to allow for proper future growth.
  - Definitive surgery for infantile Blount’s disease should be done before 5 years of age, because recurrence may develop if surgery is performed after this age.
- In patients with adolescent Blount’s disease, treatment options are hemiepiphysiodysis and osteotomy. However, if insufficient growth remains for hemiepiphysiodysis to be effective, osteotomy is the best option for correction of the deformity. Hemiepiphysiodysis of an already short limb may leave the patient with a significant limb-length inequality. If such limb-length inequality will require osteotomy for lengthening, the tibia vara should be corrected by osteotomy for angular and linear correction with external fixation.
The objective of the osteotomy is to obtain a neutral mechanical axis with a horizontal knee joint. Many different types of osteotomies have been described for the treatment of adolescent Blount’s disease, including opening and closing wedge osteotomies, dome osteotomies, and oblique osteotomies.

Following the osteotomy, fixation may be achieved with external or internal fixation. The use of cast immobilization alone has been associated with a loss of correction.

Internal fixation after osteotomy for Blount’s disease has been associated with problems. Loder et al reported poor results in patients treated with internal fixation and noted many were internally fixed in malposition, likely due to difficulty in assessing intraoperative alignment. Crossed K-wires have been associated with a loss of fixation. The use of plates has been associated with stress shielding, delayed and nonunion, and hardware breakage, and requires a second surgical procedure to remove the implant.

External fixation allows for acute or gradual correction and for later adjustments as clinically and radiographically indicated. In addition, external fixation allows for correction of the coexistent leg-length discrepancy. Price et al reported the successful use of dynamic external fixation to stabilize osteotomies for tibia vara without supplemental casting. Monolateral, hybrid, or circular external fixators may be used.

In this chapter, we describe the technique for correction of adolescent Blount’s disease via osteotomy and external fixation. The external fixator used in this technique is the EBI Multi-Axial Correction System (EBI, Parsippany, NJ). This fixator allows gradual or acute correction of deformity in two planes of angulation, two planes of translation, rotation, and lengthening without the disadvantages of a ring fixator.

### Preoperative Planning

Standing lower extremity alignment radiographs are obtained (see Fig 1). The location of the CORA in the tibia in Blount’s disease cannot be determined by simply drawing two shaft lines, because the deformity is metaphyseal or juxta-articular.

If the mechanical axis method of preoperative planning is used, the mechanical axis of the proximal tibia may be estimated by extending the femoral mechanical axis (if mL DFA is normal) or by drawing the MPTA of the contralateral MPTA (if normal) or the population normal value (87 degrees).

The distal tibia mechanical axis of the tibia is represented by a line that begins at the center of the ankle and extends parallel to the shaft. If the distal tibia has insufficient shaft length on which to base the line, the line is drawn using the contralateral lateral distal tibia angle (LDTA) or the population normal value (90 degrees).

The intersection of these lines is the CORA.

If the femur also was found to be a source of deformity during the alignment test, then CORA in the femur is identified as described by Paley et al.

The technique described in this chapter is for adolescent Blount’s disease with deformity located solely in the proximal tibia metaphysis.

The external fixator used in this technique can be applied in three different locations with respect to the CORA: CORA-centric, CORA-perpendicular, and CORA-proximal.

- The CORA-centric method places the fixator hinge directly over the CORA and minimizes unintended translation.
- The CORA-perpendicular application places the fixator hinge on the bisector of the deformity, which, when placed on the convex side of the deformity, produces simultaneous lengthening during angular correction. CORA-perpendicular application is advisable only when lengthening is required.
- The CORA-proximal application places the hinge near the CORA. This application is used when the hinge cannot be placed on the CORA or the bisector and relies on the flexibility of the hinges and translation screws to correct secondary translation.

### Positioning

The patient is placed supine on a radiolucent table. The use of an OSI table with Jackson imaging top (Orthopaedic Systems, Inc, Union City, CA) permits fluoroscopic images to be taken with minimal difficulty. A bump may be placed under the ipsilateral buttock.

A tourniquet typically is not used, because the thigh circumference of patients with Blount’s disease often is too large for a tourniquet to be used effectively.

The entire lower extremity is prepared and draped. The toes are left uncovered so that muscle contraction caused by inadvertent nerve irritation during pin placement is visible.

### Approach

The procedure is divided into fibular osteotomy, external fixator application, proximal tibia osteotomy, and completion of the surgery. Prophylactic fasciotomies are performed during exposure for the fibular and tibial osteotomies.

- The lateral approach to the fibula is used for the fibular osteotomy and lateral compartment fasciectomy. Small medial and lateral incisions are made for the tibial osteotomy, and the anterior compartment is released from the lateral incision.
- The surgeon must have thorough knowledge of the cross-sectional anatomy of the lower leg and the half-pin positions of safety.

### Surgeries

- **Fibula Osteotomy**
  - A longitudinal incision is made just lateral to the fibula at the intersection of the middle and distal thirds of the lower leg. Dissection is carried down to the deep fascia.
  - A prophylactic subcutaneous lateral compartment fasciectomy is then performed. Care is taken to avoid injury to the superficial peroneal nerve and its branches.

- **Tibial Osteotomy**
  - The peroneus longus and peroneus brevis muscles are visualized. These muscles are then retracted either anteriorly or posteriorly (depending upon exposure), and the fibula is visualized. Subperiosteal exposure of the fibula is then developed using a Cobb elevator or right-angle, and retractors are placed around the fibula to protect the soft tissues.
Chapter 30  SURGICAL MANAGEMENT OF BLOUNT’S DISEASE

TECHNIQUES

■ The tibia is corrected in the direction of valgus. Because the fibula is lateral to the tibia, correction will push the fibula proximally.
■ To prevent damage to the peroneal nerve at the proximal fibula, a 1-cm segment of bone is removed from the fibula. Oblique cuts in the fibula are made with the most proximal end aspect of the cut in the posterior edge of the fibula (TECH FIG 1). The cut is made carefully so that the saw is not inadvertently pushed past the posteromedial edge of the fibula with resultant injury to the peroneal artery.
■ Wound closure is performed at this point, because this is easier to do before the external fixator is applied.

External Fixator Application
■ The external fixator can be assembled before the procedure begins or just before application.
■ A rotating arc is selected that will allow for correction of coexisting rotational deformity or rotation inadvertently caused by misplacement of the fixator.
■ The ring size (130, 150, 180, or 220 mm) is based on the leg circumference at the level of the proximal tibia.
■ The arc should match the curvature of the anterior proximal tibia with two fingerbreadths between the ring and the leg.
■ The adult multiaxial correction (MAC) central component is then attached to the center of the rotating ring such that the primary arc on the MAC central component is facing anteriorly.
■ The MAC female adapter is placed at the other end of the MAC central component, and the telescoping arm is attached to the female adapter.
■ The primary hinge of the MAC central component is adjusted so that the fixator matches the angular deformity of the tibia.
■ In the example illustrated in this section, the MAC is applied in the CORA-centric location.
■ The CORA, as identified during preoperative planning, is localized under fluoroscopy, and an appropriately sized guide pin (supplied with the MAC) is placed from anterior to posterior into the CORA (TECH FIG 2A).
■ The guidewire should be perpendicular to the tibial diaphysis. Although placement of the guidewire exactly into the CORA can be difficult, the multiaxial or translation and rotation ability of the MAC device can correct any secondary deformity due to misplacement of the MAC off the CORA.

TECH FIG 1 • An oblique 1-cm wedge is removed from the fibula.

A. The tibia is corrected in the direction of valgus. Because the fibula is lateral to the tibia, correction will push the fibula proximally.
B. Oblique cuts in the fibula are made with the most proximal end aspect of the cut in the posterior edge of the fibula.
C. The cut is made carefully so that the saw is not inadvertently pushed past the posteromedial edge of the fibula with resultant injury to the peroneal artery.
D. Wound closure is performed at this point.

TECH FIG 2 • A. Fluoroscopy is used to localize the CORA (which was identified during preoperative planning). B. Sterile web roll padding is placed over the guidewire to serve as a spacer. C. The MAC external fixator is placed on top of the spacer. D. Two or three bone screws are placed in the proximal tibia. E. The length and angulation of the MAC external fixator are adjusted to match the deformity. F. Three bone screws are placed in the tibia shaft.
Sterile Webrik padding (The Kendall Company, Mansfield, MA) is then placed around the K-wire to serve as a two-fingerbreadth spacer (TECH FIG 2B).

The centering hole of the primary hinge of the MAC fixator is placed over the K-wire so that the fixator rests on top of the spacer (TECH FIG 2C).

Universal screw carriages are locked onto the rotation arc and used as guides for placement of two or three proximal screws.

Three proximal half-pins are then placed in the safe zones of the proximal tibia.

At least one pin is placed from anteromedial to posterolateral and one is placed from anterolateral to posteromedial.

The pins are placed distal to the physis (which may be open).

Holes are predrilled bicortically with the 4.8-mm drill bit, and 6.0-mm pins are placed.

We prefer to use hydroxyapatite-coated pins to reduce the risk of loosening and, therefore, infection. Pin size typically is around 60 mm thread length and 160 to 180 mm overall length (TECH FIG 2D).

The size of the bone screw depends on the size of the patient, the tibia at the level of screw insertion, and the size of the arc chosen.

The carriages are tightened after the pins are placed. The MAC is then adjusted to the tibial deformity, ensuring that the distal bone screw block is parallel to the distal tibial diaphysis at the medial subcutaneous face of the tibia (TECH FIG 2E).

Three distal half-pins are placed through the telescoping arm in the midshaft of the tibia (TECH FIG 2F). Pin size typically is 120 mm overall and 40 mm of thread length.

If the MAC is aligned such that the pins placed through the telescoping arm will not go through the tibia, the CORA pin should be removed and the device rotated so that the pins are aligned. (If this is done, rotation must be corrected first before the remainder of the deformity is corrected).

At this point, all the pins (bone screws) have been inserted.

**Tibia Osteotomy**

Using the MAC external fixator, placing the pin at the CORA allows deformity correction to occur at the CORA. The osteotomy does not have to be made at the CORA. It should be performed just below the insertion of the tibial tubercle, decreasing the risk of damage to the nearby physis and joint line. Placement of the osteotomy below the tibial tubercle will also avoid pulling the patella distally during distraction.

The tibial osteotomy may be performed using one of several different techniques. Our preference is to perform the osteotomy through small transverse anteromedial and anterolateral incisions with a Gigli saw passed subperiosteally.

Fluoroscopy is used to identify the metaphyseal-diaphyseal junction where the osteotomy will be made.

The guide pin is removed.

A 2-cm transverse incision is made on the medial and lateral aspects of the anterior tibia at the level for the osteotomy. The incision is made transversely to avoid skin injury from the Gigli saw.

From the lateral incision, dissection is carried down to the fascia of the anterior compartment.

A prophylactic subcutaneous release of the anterior compartment is then performed through this incision.

A hemostat is used to expose the tibia subperiosteally at the level of the osteotomy (TECH FIG 3A).

Umbilical tape is then held taut by a right-angle and passed, subperiosteally, around the back of the tibia (TECH FIG 3B). A hemostat is placed posterior to the tibia from the opposite side, and the umbilical tape is grasped and pulled out the opposite side of the leg (TECH FIG 3C).
To verify that the saw has not been placed around the anterior or posterior tibial arteries, the ends of the umbilical tape are pulled taut while palpating the pedal pulses for occlusion. Care should be taken to avoid shredding the umbilical tape, which can leave foreign material behind.

The Gigli saw is then tied to the umbilical tape to pass the saw around the back of the tibia.

The osteotomy is then performed with the Gigli saw.

Care is taken to avoid injury to the skin.

Fluoroscopy is used to verify the completion of the osteotomy and alignment of the proximal and distal fragments with the external fixator.

**Completion of Surgery**

The lengthening device is then inserted onto the telescoping arm and turned such that it slides into the telescoping arm (TECH FIG 4A). Both screws of the lengthening device are then tightened.

All screws of the external fixator are then given their final tightening.

All wounds are closed, and a sterile dressing is applied (TECH FIG 4B).

Acute correction typically is not performed if there is risk of stretching neurovascular tissues.

During the first postoperative week, the patient learns to walk with crutches, 10 pounds, partial weight bearing.

On the 8th day, the patient is taught to lengthen through the compression distraction mechanism at a rate of one 90-degree turn of the Allen wrench four times a day. This will cause lengthening of 1 mm per day.

On the 14th day, a radiograph should show that the ends of the osteotomized tibia are separated by a distance of about 7 mm (TECH FIG 4C,D).

Angular correction can now begin. The patient is taught to place the Allen wrench into the primary angulation screw and turn 90 degrees in the direction for angular correction. This 90-degree turn will correct...
Patients must be followed closely during correction so that malalignment does not occur. Pin site infections must be recognized and treated appropriately. Radiographs must be evaluated carefully and systematically so that the location of the CORA and coexistent deformities of the femur or sagittal plane are identified. Careful neurovascular examinations must be performed postoperatively. A correct diagnosis of Blount’s disease must be made before treatment is initiated. Treatment alternatives, including hemiepiphysiodesis (if there is sufficient growth remaining), must be discussed with the patient and family.

### TECHNIQUES

The correction phase begins with lengthening the leg by 7 to 8 mm at a rate of 1 mm per day (0.25 mm four times per day) to separate the bone ends. Angulation is then corrected. The patient is evaluated clinically and radiographically to follow correction of the mechanical axis. Scanograms can then be obtained to determine leg-length inequality, which can be corrected by lengthening with the fixator. The rotational deformity (internal tibial torsion) is corrected last. Placing white adhesive tape with arrows onto the device helps patients remember how to turn the screws appropriately for angular, linear, and rotational correction.

Weight bearing is increased during the consolidation period. The consolidation period is approximately twice the correction period. Most patients treated with this technique for adolescent Blount’s disease will have the external fixator on for 3 to 4 months. They can walk with crutches initially and progress to full weight bearing as the osteotomy heals. They can shower within 3 days of application of the fixator.

When radiographs show that the osteotomy and distraction gap have healed, the external fixator is removed. Removal can be done in the office or in the operating room. Considerable torque is required to remove hydroxyapatite pins, and this must be done in the operating room with adequate sedation and analgesia.

</tbody>
</table>

### POSTOPERATIVE CARE

- Patients are admitted to the hospital and monitored closely for signs and symptoms of neurovascular injury and compartment syndrome.
- Patients initially are allowed touch-down weight bearing only. Range-of-motion exercises are begun immediately.
- Pin care is begun on postoperative day 2. Patients are instructed on the signs and symptoms of pin site infections.
- No adjustments or corrections are made to the external fixator for the first 7 days. A 7-day latency allows fracture callus to develop at the site of the osteotomy. Then the correction phase is begun.
- The correction phase begins with lengthening the leg by 7 to 8 mm at a rate of 1 mm per day (0.25 mm four times per day) to separate the bone ends. Angulation is then corrected. The patient is evaluated clinically and radiographically to follow correction of the mechanical axis. Scanograms can then be obtained to determine leg-length inequality, which can be corrected by lengthening with the fixator. The rotational deformity (internal tibial torsion) is corrected last. Placing white adhesive tape with arrows onto the device helps patients remember how to turn the screws appropriately for angular, linear, and rotational correction.
- When radiographs show that the osteotomy and distraction gap have healed, the external fixator is removed. Removal can be done in the office or in the operating room. Considerable torque is required to remove hydroxyapatite pins, and this must be done in the operating room with adequate sedation and analgesia.

### OUTCOMES

- Because adolescent Blount’s disease is relatively uncommon, there are few outcome studies in the literature.
- Price et al7 reported on the treatment of 31 tibiae in 23 patients with dynamic external fixation. All osteotomies healed. There was an average correction of 20 degrees, and no postoperative loss of correction occurred.

### COMPLICATIONS

- High complication rates have been reported for proximal tibial osteotomies.
- Steel et al8 reported a 20% rate of neurologic complications in 46 tibial osteotomies. The neurologic complications are related to the location of the osteotomy, which must be done in the metaphysis to avoid damaging the proximal tibial epiphysis.
- Deformity correction at this level can stretch or compress the anterior tibial artery because of its proximity to the tibia at that level. While arterial stretch or compression is more common than laceration or edema in anterior compartment following correction, prophylactic fasciotomies of the anterior and lateral compartments are still indicated to decrease the risk of neurovascular complications.
- Other complications include delayed union and nonunion.
REFERENCES

DEFINITION

Epiphysiodesis (epiphysio–diaphyseal fusion) is an established method to treat a mild limb-length discrepancy (2 to 5 cm) in children.

With epiphysiodesis, growth of a longer extremity is inhibited by prematurely arresting a selected physis so that the remaining growth of the shorter extremity may approximate or equalize limb lengths at maturity.

The open epiphysiodesis technique was first described by Phemister in 1933 and modified by White in 1944. “Percutaneous epiphysiodesis” was reported first by Bowen and Johnson in 1984.

Subsequently, other variations of percutaneous epiphysiodesis with their outcomes have been reported.

When equalizing limb-length discrepancy by epiphysiodesis, caution should be used in terms of the patient’s age at operation, the physis selected for premature closure, and the number of physis necessary to correct the discrepancy.

Useful data in decision making include:

- Body length from head to foot (to determine percentile of height)
- Length of the bones of the lower extremity (to determine degree and source of discrepancies)
- Skeletal maturation age (to determine potential remaining growth), and the disease course that caused the limb inequality (to determine the predictability of remaining growth)
- Proper patient age for timing of the epiphysiodesis may be determined by several methods, including the Green and Anderson method, the Mosley straight-line method, the “rule of thumb” method, and the multiplier method.
- Physseal stapling is an alternative operative procedure for correcting limb inequality by retarding growth in a longer extremity. The goal of physseal stapling is to retard growth of a physis with staples until the desired correction is obtained, after which the staples can be removed, with physseal growth resuming until maturity.

ANATOMY

An epiphysiodesis can be achieved by ablation of the medial and lateral peripheral margins of the physis. These subsequently form bony bars that restrict growth, and then the central aspect of the physis closes spontaneously, resulting in a total epiphysio–diaphyseal fusion.

Caution is required in the femur distally because the epiphysis is narrow at the central area of the physis.

Posteriorly the neurovascular structures are deeply positioned within the condyles, and anteriorly the patella–femoral joint is close.

Injury to the neurovascular structures may be catastrophic. Therefore, I prefer the peripheral margin ablation technique as described here, in which the central area of the physis remains undisturbed.

The common peroneal nerve at the knee runs obliquely along the lateral side of the popliteal fossa, close to the medial border of the biceps femoris muscle and the lateral head of the gastrocnemius muscle, toward the head of the fibula.

The nerve winds posteriorly around the neck of the proximal fibula and passes deep to the peroneus longus muscle, where it divides into the superficial and deep peroneal nerves.

PATHOGENESIS

The etiology of a limb-length discrepancy may be important in determining the appropriate patient age at which the percutaneous epiphysiodesis is performed.

Shapiro reported different patterns of growth inhibition that may cause shortening of a limb.

Predictable growth of the shorter extremity is required to achieve optimal results with a percutaneous epiphysiodesis.

NATURAL HISTORY

After a percutaneous epiphysiodesis, bony bridges form at the peripheral margins of the physis both medially and laterally. These bony bars prevent further physeal growth.

After peripheral bony bar formation following a percutaneous epiphysiodesis, the central area of the physis (unoperated area) will spontaneously close within 6 to 8 months.

The scientific reason for this spontaneous closure of the central area is unclear. Confusion exists in that staples do not cause physseal closure, whereas peripheral bony bars from an epiphysiodesis result in progressive physseal closure.

I have studied this phenomenon but found no definitive causes.

Reversal of limb-length discrepancy could occur if the shorter limb (contralateral) were to overgrow the epiphysiodesis limb (ipsilateral) before maturity.

I have not had a patient have this complication, but follow-up until skeletal maturity is advised.

By following growth until maturity, this potential problem may be detected and a contralateral epiphysiodesis may prevent a limb-length discrepancy at maturity.

A percutaneous epiphysiodesis can be used in combination with contralateral limb lengthening in patients with severe shortening.

In major limb-length discrepancies, lengthening may not be able to correct the full discrepancy, and remaining small discrepancies of 2 to 5 cm may be more easily corrected by a contralateral percutaneous epiphysiodesis than by a secondary ipsilateral lengthening.

After leg-lengthening procedures, growth of the lengthened limb may be retarded or occasionally stimulated.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The patient history and physical examination should include the following:
  - Etiology of the limb-length discrepancy
The patient’s height (percentile of height)\(^8,10\)
- The total height and the leg lengths (in centimeters) are measured. The percentile of height is then determined and used to plot limb-length predictive charts.

- The level of maturation, based on the appearance of secondary sexual characteristics and the Tanner scale.\(^11\) Caution should be used if the clinical maturation scale differs significantly from the Greulich and Pyle skeletal developmental age.
- Foot height (foot height is not typically considered in radiographs that measure limb length)
- The patient’s “bone age” (expressed in years) using the Greulich-Pyle method. Caution should be used if the chronological age differs from the “bone age.”
- Radiographs of the limbs are obtained to measure the tibia and femur (expressed in centimeters). These measurements are plotted on growth charts to predict the discrepancy at maturity and to determine the age for epiphysiodesis.
- Blocks of differing thicknesses are placed under the foot of the shorter limb until the pelvis is level to determine the length discrepancy (expressed in centimeters). This method also helps evaluate discrepancies in the foot that are not reported by radiographs.
- After length measurements of both limbs are obtained, the ratio of femur to tibial discrepancy of the normal to abnormal limb is determined.
- A disease diagnosis can be made with Shapiro developmental patterns.\(^22\) However, proportional inhibition of growth is more predictable, while disproportional growth is difficult to predict.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**
- Skeletal age determination by the Greulich and Pyle method\(^11\)
- Green-Anderson method of predicting limb-length discrepancy (my preference)\(^2,3\)
- Mosley graphic method of predicting limb-length discrepancy\(^16\)
- Multiplier method of predicting limb-length discrepancy\(^1,18\)
- Menelaus “rule of thumb” method\(^15\)
- I prefer the Mosley straight-line method because growth inhibition is expressed graphically, multiple data entries can be charted to help predict growth more accurately, and the method is easy to calculate in a brief outpatient visit.
- I perform a proximal fibular epiphysiodesis in addition to the proximal tibial epiphysiodesis if the final discrepancy between the tibia and fibula is anticipated to be more than 1 cm.
- If the discrepancy is anticipated to be less than 1 cm, I do not perform a proximal fibular epiphysiodesis and have not detected a clinical problem with such a mild discrepancy.

**NONOPERATIVE MANAGEMENT**
- No treatment is required if the limb-length discrepancy is less than 2.5 cm at maturity.
- A shoe lift can be used to treat mild limb-length discrepancies of more than 2.5 cm.
- Often a lift is used in children until an appropriate skeletal age is reached to perform an equalization procedure.
- A prosthesis may be necessary if deformities are so severe that adequate length or ambulatory ability cannot be achieved by operative methods.
- Surgery may be necessary to provide an appropriate stump for the prosthesis, and a percutaneous epiphysiodesis is used occasionally to achieve correct stump length.

**SURGICAL MANAGEMENT**
- Epiphysiodesis is most commonly performed at the distal femoral physis or the proximal Tibia–fibula physis.
- Ablation of the peripheral margins both medially and laterally in a physis causes bony bridges to form between the epiphysis and metaphysis that accomplish growth inhibition in that physis (epiphysiodesis).
- This can be accomplished by different techniques and instruments, which include a curette, a drill, a burre, a reamer, and a circular tube saw.
- I prefer a curette because surgeon control is easy and the curette can be passed percutaneously. I have used various instruments, but drills and burrs tend to burn and occasionally grab tissue, and reamers and circular saws require a larger incision (really not percutaneous, almost the size of a typical open epiphysiodesis).
- A bony bridge needs to form only at the peripheral margins of the physis both medially and laterally to accomplish an epiphysiodesis. The central part of the physis does not require treatment because it will close spontaneously.
- The stability of the bone is maintained postoperatively and the patient may continue to ambulate.
- I restrict sports for 6 weeks to reduce the possibility of a fracture.

**Preoperative Planning**
- Anticipated remaining growth is determined by one of the following methods:
  - Green-Anderson method\(^10\)
  - Mosley graphic method\(^16\)
  - Multiplier method\(^18\)
  - Menelaus “rule of thumb” method\(^15\)
- I prefer the Mosley straight-line method because growth inhibition is expressed graphically, multiple data entries can be charted to help predict growth more accurately, and the method is easy to calculate in a brief outpatient visit.
- I perform a proximal fibular epiphysiodesis in addition to the proximal tibial epiphysiodesis if the final discrepancy between the tibia and fibula is anticipated to be more than 1 cm.
- If the discrepancy is anticipated to be less than 1 cm, I do not perform a proximal fibular epiphysiodesis and have not detected a clinical problem with such a mild discrepancy.

**Positioning**
- Image intensification
- Supine position
- The limb is prepared and draped up to the proximal thigh into a sterile field. A tourniquet is placed on the proximal thigh but is not inflated unless bleeding occurs.

**Approach**
- Femoral epiphysiodesis at distal physis
  - Longitudinal incisions of 3 mm (stab incisions) medially and laterally in the skin at the level of the physis at its peripheral area
- Tibial epiphysiodesis at proximal physis
  - Longitudinal incisions of 3 mm
  - Medially the incision is 3 mm at the level of the physis at its peripheral area.
  - Laterally the incision is 3 mm at the level of the physis and at the anterior border of the fibula.
- Fibular epiphysiodesis at the proximal physis
  - The same incision is used for the fibular epiphysiodesis as for the lateral physeal area of the tibia; however, in the epiphysiodesis of the fibula the curette is directed differently to avoid injury to the common peroneal nerve (described below). (See above section on anatomy.)
EPIPHYSIODESIS OF THE FEMORAL PHYYSIS DISTALLY OR THE TIBIAL PHYYSIS PROXIMALLY

Preparation of the Physis
- A metal marker is placed over the skin and under the image intensifier, and the level of the physis is identified at its peripheral area (either medially or laterally) (TECH FIG 1A).
- A 3-mm skin incision is made with a scalpel at the level of the physis plate on the peripheral side (medially or laterally) (TECH FIG 1B).
- Under image intensification control, a 3-mm-wide osteotome is directed through the skin incision to make a longitudinal split in the periosteum–cortex, and the physeal plate is then penetrated to a depth of about 0.5 cm (TECH FIG 1C,D).
- The osteotome is rotated to create a hole in the physis and is then withdrawn.

Physeal Plate Ablation
- A 3-mm oval curette is advanced through the skin into the hole of the physis (TECH FIG 2A).
- Under image intensification control, the curette is rotated and advanced to the level of the inner third of the physis (TECH FIG 2B).
- The curette is then swept cephalad and caudad in the physis to ablate the peripheral third of the physis, leaving the middle third intact (TECH FIG 2C).
- Specific surgical attention is directed toward adequate ablation of the most peripheral aspect of the physeal plate (TECH FIG 2D–F).
- The same operative process is repeated on the opposite side of the physeal plate (medially or laterally), again sparing the middle third of the physeal plate.
- The wound is closed by suture (typically one absorbable suture) (TECH FIG 2G).

(continued)
Epiphysiodesis of the Fibula Proximally

- The same incision is used to perform the epiphysiodesis of the fibula as the proximal physis of the tibia laterally.
- To avoid injury to the common peroneal nerve with a percutaneous epiphysiodesis of the proximal fibula, direct the curette into the anterosuperior area of the proximal epiphysis and then inferiorly into the physis of the proximal fibula (TECH FIG 3A).
  - The most superior extent of the fibular epiphysis proximally is usually at the level of the tibial physis.
  - The curette is used to ablate the entire central area of the physis of the fibula to achieve the epiphysiodesis (TECH FIG 3B).
- The surgeon should not exit the cortex of the fibula as the central area is ablated.
- The 3-mm incisions are each closed with a single suture.
- The incision is covered by an adhesive strip and bandage.
- A knee immobilizer foam brace is applied and maintained postoperatively.
- The elastic of the knee immobilizer adds very mild compression to the incision and helps prevent a hematoma or edema.
- The knee immobilizer brace should not be applied with a force that impedes circulation.
PEARLS AND PITFALLS

| Discrepancy between bone age and chronological age | In such cases, I prefer to use the bone age. Another choice is to use a stapling technique (or figure 8 plate-screw), which preserves the physis, rather than epiphysiodesis. |
| Discrepancy between predictive charts and parental opinion | Use several methods to substantiate the outcome. Also, I prefer to delay the epiphysiodesis for a short period to ensure that the limb lengths do not reverse the discrepancy. Another choice is to use a stapling technique. |
| Neuromuscular weak and short extremity | I prefer to have the weak extremity slightly shorter at maturity; about 1 to 1.5 cm short seems acceptable. |
| Follow-up to maturity | Some diseases tend to produce growth in a manner that is poorly predictable. If the limb lengths correct and remaining growth will cause a problematic (reversal) discrepancy, I would perform a contralateral epiphysiodesis. |

POSTOPERATIVE CARE

- Postoperatively the leg is protected by a knee immobilizer brace, and full weight bearing with crutch support is allowed.
  - The patient may usually be discharged within the same operative day (outpatient surgery).
  - The knee immobilizer is used for 3 to 4 weeks to protect the extremity from fracture.
  - The scars of the percutaneous epiphysiodesis are small and have an acceptable appearance (FIG 1).
  - Radiographs are performed about 4 to 6 months postoperatively to ensure adequate healing.
  - Bony bars at the peripheral margins of the physis are usually observed radiographically by 6 months postoperatively.
  - Total closure of the physis occurs 8 to 12 months postoperatively.
  - Correction of the leg-length discrepancy may be determined by periodic radiographs and clinical examinations.
  - During postoperative evaluations the extremity should be evaluated to ensure appropriate length correction and to watch for an angular deformity.
  - Lack of appropriate closure may result in undercorrection and asymmetric closure causes angulation.

OUTCOMES

- Recently I reviewed the outcome of percutaneous epiphysiodesis as described above in a consecutive series of 97 patients (56 girls and 41 boys) with a mean skeletal age of 12.6 years (range 10 to 16 years) at surgery. All patients were followed until skeletal maturity, a mean of 3.8 years. The mean residual limb-length discrepancy in 88 patients at maturity was 1.3 cm (I consider normal to be a lower-limb discrepancy of less than 2.5 cm). In nine patients, the epiphysiodesis was combined with a femoral lengthening or femoral shortening.
  - The Moseley straight-line method accurately and efficaciously predicted the timing for percutaneous epiphysiodesis in all but one patient, who had unpredictable growth from hemihypertrophy secondary to a hemangiomatosis.
  - Horton and Olney12 reported the results of 42 percutaneous epiphysiodeses in 26 patients. Physeal arrest developed in all cases and no angular deformities occurred. They considered the percutaneous epiphysiodesis to be reliable and safe. Stated advantages include a cosmetic scar, short hospital stay, low incidence of complications, and reliability.
  - Canale and coworkers6 reported on 13 children treated by a percutaneous epiphysiodesis; growth plate fusion occurred in all cases. They used a pneumatic burr under image intensification to perform the procedure.
  - Brax and Gille7 performed a percutaneous epiphysiodesis using a drill and radiographic control in 10 children. They had good results in all but one case and considered the procedure to be minimally traumatic, cosmetically preferable, and safe.
  - Craviari and colleagues7 reported the results of 60 cases followed to skeletal maturity who were treated by a percutaneous epiphysiodesis. They concluded that the procedure was satisfactory and complications were rare. Complications comprised hematoma in 2 cases, need for surgical revision in 10 cases, limb deviation in 4 cases, and inverted discrepancy in 2 cases.
  - Gabriel and associates8 reported the results of 29 patients who underwent 56 physeal procedures with a percutaneous epiphysiodesis. The procedure lasted a mean of 36 minutes, and in all patients a physeal closure developed. No unplanned angular growth, no deep infections, and no cases of joint stiffness were reported.
  - Kemmitz and coworkers13 performed a retrospective review of 57 patients who underwent percutaneous epiphysiodesis. They reported no significant operative problems. A final limb-length discrepancy greater than 2 cm was seen in 17.5% of the cases, and they concluded the timing of the procedure remains the main problem.
  - Macnicol and Gupta14 reported 35 cases of epiphysiodesis in which a cannulated tube saw was used to ablate the physis. The mean anticipated discrepancy was 3.3 cm, and at maturity the discrepancy averaged 0.7 cm. One patient had slight overgrowth of the fibula and another had an unsightly scar; otherwise the results were favorable.
  - Ogilvie and King15 used a low-speed, high-torque drill to create an epiphysiodesis in seven children. This technique required a 1-cm incision. There were no cases of failure of physeal...
fusion, no infections, no angular deformity, and no restriction of joint motion.

- **Porat and coworkers** performed epiphysiodesis in 20 children, with good results in 90% of the patients. They recommended the Moseley straight-line graph and percutaneous epiphysiodesis.

### COMPLICATIONS
- Errors in predicting growth
- Infection
- Angulation
- Lack of physeal closure
- Temporary exostosis formation (believed to develop as bone forms in the elevated periosteum)
- Hematoma
- Neurovascular injury

### REFERENCES
DEFINITION
- A physeal bar, or partial premature physeal arrest, is an osseous connection that forms across a physis and has the potential to affect physeal growth.4
- Partial physeal arrest may result in three clinically significant consequences:
  - Angular deformity
  - Limb-length discrepancy
  - Bone-length discrepancy in a two-bone limb segment such as the forearm or leg.
- When evaluating a patient with a physeal bar, one must critically consider whether there is sufficient growth remaining to cause a clinically significant length discrepancy or angular deformity.
- One should consider the linear magnitude of anticipated growth remaining, as well as the years of remaining growth.

ANATOMY
- The normal physis acts as a physical cartilage barrier separating the trabecular bone of the epiphysis from the metaphysis (FIG 1).
- Blood vessels typically do not traverse the physis, necessitating an independent blood supply for the epiphysis and metaphysis.1

PATHOGENESIS
- Physeal bars form when the cartilage barrier is breached as the result of trauma, infection, or cell death and trabecular bone heals in continuity between the epiphysis and the metaphysis across the physis.6
- Variation in physis anatomy may predispose certain physes to physeal bar formation. For example, the distal radius physis is relatively two-dimensional and uniplanar, while the distal femoral physis has a more complex three-dimensional biconcave configuration.
- Distal radius physeal fractures are quite common, yet subsequent premature physeal bar formation is relatively rare. In contrast, distal femoral physeal fractures are uncommon but distal femoral physeal bar formation is much more prone to occur after injury.
- The three-dimensional configuration of the distal femoral physis contributes to the considerable energy required to fracture through the distal femoral physis, and the complex geometry increases the likelihood for violation of the physeal cartilage barrier between epiphyseal and metaphyseal bone, thereby increasing the risk of partial physeal bar formation after injury.
- Breach of the physeal cartilage barrier is most frequently caused by fracture, followed by infection.
- Less common pathogenesis for partial physeal bar formation may occur when the germinal or proliferating cells on the epiphyseal side of the physis plate are injured by ischemia, infection, heat, laser, electricity, or other insult. As the germinal cells die and cell division in this region of the physis stops, partial physeal bar formation may occur.3

NATURAL HISTORY
- In almost all situations, once a physeal bar has formed, length discrepancy, angular deformity, or both will continue to increase so long as the patient is skeletally immature and the affected physis (or its contralateral counterpart) continues to grow.

PATIENT HISTORY AND PHYSICAL FINDINGS
- Questioning the patient quickly reveals the cause for physeal bar formation in most cases. The most common causes of physeal bar formation, fracture and infection, are typically memorable events that the patient can quickly recall.
- The examiner should ask the patient and family if they have noticed a progressive limb-length discrepancy, limp, angular deformity, or bony prominence; this may confirm the presence of a physeal bar.
- Ideally the orthopaedist is aware of the physeal injury, is anticipating possible physeal bar formation after injury, and is

FIG 1 • The physis acts as a physical barrier separating the trabecular bone of the epiphysis from the trabecular bone of the metaphysis. The physis also acts as a barrier to blood flow, separating the epiphyseal blood supply (a) from the metaphyseal blood supply (b). Magnification of the physis illustrates the four physeal cell layers: the resting cell zone (c), the proliferating cell zone (d), the hypertrophying cell zone (e), and the enchondral ossification zone (f). Insults that breach the physical separation between metaphyseal and epiphyseal trabecular bone, that significantly compromise epiphyseal blood flow, or that critically injure the resting or proliferating cell layers may result in physeal bar formation.
Chapter 32  EXCISION OF PHYSEAL BAR

monitoring the patient at 6-month intervals with clinical examination and radiographs.

- The patient is examined for lower extremity limb-length discrepancy using blocks of known height under the shorter limb until the pelvis is level.
- The patient is also examined for lower extremity angular deformity. The alignment at knee and ankle is assessed and compared to the contralateral limb.
- The patient is also examined for upper extremity limb-length deformity. Length of the affected limb is compared to that of the contralateral limb.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Appropriate imaging is critical for the evaluation of a potential physeal bar. Initial imaging is performed to determine whether the patient has sustained a clinically significant physeal injury and therefore should demonstrate limb-length discrepancy and angular deformity.
- True scanograms use a slit beam that is perpendicular to the patient that scans the length of the limb and therefore has no magnification. The scanogram provides limb length and angular information with a single image (**FIG 2A**).
- A teleoroentgenogram, or full-length, standing, hip-to-ankle radiograph taken at a distance, does result in some magnification of the limb.
  - By placing blocks of known height beneath the shorter limb, a teleoroentgenogram can also provide information about length and angular deformity with a single radiograph.
  - A ruler or magnification markers can also be placed next to the limb to allow more accurate measurement of limb length.
- Orthoroentgenograms (separate exposures of the hip, knee, and ankle on a single film with a ruler) or CT scout images can be used to determine limb length.
  - These must be supplemented by a full-length image of the limb to assess angular deformity.
- If the distal tibial physis is the injured physis in question, standing anteroposterior (AP) and lateral ankle radiographs are indicated to assess angular deformity.
- If limb-length discrepancy or angular deformity is confirmed, additional imaging is indicated to determine the size and location of the physeal bar.
- Either fine-cut CT or MRI may be used, and axial, coronal, and sagittal plane images are obtained.
  - The CT or MRI images are used to create a map that illustrates the location and approximate cross-sectional area of the physeal bar (**FIG 2B,C**).
  - The relative cross-sectional area of the bar is important because physeal bars occupying greater than 50% of the cross-sectional area of the physis have a less favorable result after resection. Excision of bars greater than 50% of the physeal cross-sectional area may still be indicated in young patients, such as a 5-year-old patient with a 65% bar of the distal femoral physis.
- A skeletal age radiograph of the hand and wrist may be helpful in older patients if one is trying to determine if there is sufficient growth remaining for physeal bar resection to be indicated.

**DIFFERENTIAL DIAGNOSIS**

- Physeal injury without growth abnormality
- Idiopathic limb-length discrepancy
- Developmental cause for limb-length discrepancy or angular deformity
- Blount disease
- Madelung deformity of the distal radius

**NONOPERATIVE MANAGEMENT**

- Anticipated lower extremity limb-length discrepancy of less than 1 cm requires no treatment.
- The simplest means of correcting a lower extremity limb-length discrepancy is to place a lift either inside or on the bottom of the shoe on the shorter limb.

---

**FIG 2 • A.** A true scanogram uses a slit beam of radiation that moves or “scans” down the length of the extremity. Because the radiation beam always remains perpendicular to the film, there is no magnification of the radiographic image, and distances can accurately be measured directly on the radiograph. The entire limb is included on the image, so angular deformity can be measured as well as length. Using multiple CT or MRI images (**B**), a map of the physeal bar is created (**C**) and the relative cross-sectional area of the bar is estimated.
Anticipated lower extremity discrepancy of 1 or 2 cm is most easily treated with a shoe lift inside the shoe.

Discrepancy greater than 2 cm treated nonoperatively is typically managed by a lift placed on the shoe sole.

There is no effective nonoperative treatment to correct clinically significant angular deformity caused by a physeal bar.

**SURGICAL MANAGEMENT**

- Lower extremity physeal arrest resection should be considered in patients with an anticipated growth remaining from the affected physis of about 2 years or 2 cm.
- Pure length discrepancy in the upper extremity caused by a physeal bar in the proximal humerus causes little functional problem, and anticipated discrepancy of up to 5 cm may be observed.
- Bone-length discrepancy in a two-bone limb segment such as the forearm or leg is less well tolerated. Anticipated bone-length discrepancy of greater than 1 cm at the wrist may warrant surgical treatment either by physeal bar resection or complete epiphysiodesis of both bones to prevent bone-length discrepancy.
- Surgical treatment for a physeal bar may consist of physeal bar resection, complete epiphysiodesis of the involved physis, epiphysiodesis of the adjacent bone in leg or forearm, epiphysiodesis of the contralateral physis, or an approach combining more than one of these. The surgical technique for physeal bar resection alone will be discussed below.
- If the decision has been made to perform physeal bar excision and an angular deformity is present, one is faced with the question as to whether an osteotomy should be performed at the time of physeal arrest resection to correct angular deformity.
- Our philosophy is to first perform physeal bar resection alone.
- Physeal bar resection is a relatively minor procedure with rapid recovery and the potential to correct (at least partially) the angular deformity. Accurate prediction of angular correction after physeal bar resection is not possible, making it very difficult to know with certainty the degree of osteotomy angular correction to perform.
- We would prefer to perform physeal bar resection alone first, then correct any residual angular deformity when physeal growth is complete.
- At skeletal maturity, the target is no longer moving and any additional adjustment in limb length can be addressed as well.

**Preoperative Planning**

- Imaging studies are reviewed and a map of the size and location of the physeal bar is created.
- A strategy is determined to provide the safest and most direct surgical approach to the physeal bar.

**Positioning**

- The patient is positioned to facilitate a direct approach to the physeal bar. For example, if a lateral approach is determined to be the most direct and safe route to a distal femoral bar, the patient is positioned with a generous bump elevating the hemipelvis and affected limb, with a tourniquet placed on the proximal thigh.
- Fluoroscopy is used to guide physeal bar resection, so the patient must be placed on a radiolucent table in a position to facilitate AP and lateral fluoroscopic images.

**Approach**

- The particular approach for each patient is determined by the location of the physis affected by the physeal bar and the location of the bar within the physis.
- A direct approach to the bone surface at the level of the physis is used for peripheral bars.
- Central physeal bar resection is typically performed by approaching the physis through the metaphysis adjacent to the physeal bar.
- The general strategy for central physeal bar excision in a long bone is to access the bar through a metaphyseal bone tunnel, resect the bar, and place an interposition material that will prevent recurrent bar formation (FIG 3).

![FIG 3](https://example.com/fig3.png)

**FIG 3** • The general strategy for central physeal bar resection (A) is to create a cortical window (B) through which the surgeon can excise the bar (C) and then place interposition material (D) to prevent bar recurrence. (Adapted from Peterson HA. Partial growth plate arrest and its treatment. J Pediatr Orthop 1984;4:246–258.)
With the patient prepared and draped, fluoroscopy is brought into the field and the location of the physis is marked on the skin surface. Next, using a blunt pin or straight instrument, mark on the skin the desired approach trajectory to the physeal bar. Draw the skin incision line on the approach trajectory (TECH FIG 1A).

Exsanguinate the limb and incise the skin longitudinally where an internervous plane can be used. With metaphyseal bone exposed, using AP and lateral fluoroscopic imaging, consider advancing a Kirschner wire or Steinmann pin along the approach trajectory from the metaphysis into the center of the physeal bar. This Kirschner wire will act as a guide to the location and depth of the physeal bar (TECH FIG 1B).

Using multiple drill holes and an osteotome, create an oval cortical window in metaphyseal bone (TECH FIG 1C). Remove and save the cortical window and superficial metaphyseal bone to be used for later closure. As the tip of the reference Kirschner wire is approached, use a motorized burr to carefully remove bone until the center of the physeal bar is reached, as confirmed fluoroscopically. Within the center of the physeal bar, no physis will be seen. Under fluoroscopic guidance, use the motorized burr to carefully expand the area of resection until normal physis is encountered (TECH FIG 1D).

**TECH FIG 1 • A.** Before making a skin incision, fluoroscopy is brought into the surgical field and the surgeon draws on the skin the physis location, the physeal bar location, the surgical approach trajectory, and the skin incision location that will permit the desired approach. **B.** Under fluoroscopic guidance a Kirschner wire is advanced to the level of the physeal bar along the desired surgical approach trajectory. Multiple drill holes are then made that incorporate the Kirschner wire into the periphery of an elliptical cortical window. The Kirschner wire will act as a guide to the location and depth of the physeal bar. **C.** Multiple drill holes are connected with a narrow osteotome to create a cortical window. The window is saved and replaced during closure. (Kirschner wire guide is not shown in this photograph.) **D.** After removing metaphyseal bone with a curette, a burr is guided by fluoroscopy to expand the bar resection cavity until normal physis is visualized within the cavity. (C,D: From Peterson HA. Epiphyseal Growth Plate Fractures. Heidelberg: Springer, 2007. With kind permission of Spring Science and Business Media.)
BAR RESECTION

- Once the physis is identified within the resection cavity, the motorized burr is used to remove bone along the leading edge of the exposed physis until normal-appearing physis is exposed throughout the entire circumference of the resection cavity.
  - The exposed normal physis should appear flat and smooth (TECH FIG 2A).
  - A surgical headlight is helpful to visualize the physis within the resection cavity.
  - If a region of the resection area cannot be seen by direct vision, use a dental mirror or small joint arthroscope to visualize the physis and confirm complete physeal bar excision (TECH FIG 2B).
  - Topical liquid thrombin may be applied to the resection cavity bone surface to reduce hematoma formation, which in theory might promote recurrent bar formation.

MARKER PLACEMENT

- Place titanium markers in the epiphysis and metaphysis to facilitate later measurement of physeal growth (TECH FIG 3A).
  - Marker position in the center of the bone prevents the metaphyseal marker from becoming extraosseous with future remodeling.
  - Our preference is a titanium 0.062 Kirschner wire notched 10 mm from the tip, which can be broken off within bone (TECH FIG 3B).
  - Titanium markers avoid artifact on subsequent MRI or CT scans.

TECH FIG 2 • A. Within the resection cavity the physis should appear smooth, flat, and healthy after bar resection. B. A dental mirror is used to look back at the physis in regions within the cavity where the physis cannot be directly visualized. At the conclusion of bar resection, normal physis should be visualized as a continuous cartilage line around the full circumference of the resection cavity.

TECH FIG 3 • A. The first titanium marker has been placed centrally within the metaphysis proximal to the physis. A second marker is going to be placed within the epiphysis distal to the physis. B. A 0.062 titanium Kirschner wire notched 10 mm from the end makes an ideal radiographic marker that will not interfere with future MRI imaging. (From Peterson HA. Epiphyseal Growth Plate Fractures. Heidelberg: Springer, 2007. With kind permission of Spring Science and Business Media.)
CRANIOPLAST INTERPOSITION

- An interposition material is then placed in the physeal bar defect. Some authors have recommended fat as an interposition material, but we prefer cranioplast polymethylmethacrylate for several reasons:
  - Cranioplast has a slow polymerization rate and does not generate heat, which might be harmful to the physis.
  - Cranioplast confers immediate structural strength to the resection area, allowing full weight-bearing after surgery.
  - No loosening has ever been reported after physeal bar resection.
  - Cranioplast stays securely within the resection bed and cannot “float” out of the resection bed on hematoma.
  - An additional incision to harvest fat interposition material is avoided.
  - Cranioplast can be injected into the resection defect in its liquid state, or it can be allowed to polymerize to the consistency of putty, then gently digitally pressurized into the cancellous bone of the resection bed, preventing displacement.

FAT INTERPOSITION

- If fat is chosen as the interposition material, a donor site must be chosen.
  - Rarely, in a patient with a small physeal bar, local fat may be harvested.
  - Most patients require harvesting fat from a distant site, and the gluteal region is typically used.

- Our current indications for fat interposition material include:
  - Physeal bars caused by infection, where this is a concern for recurrent infection
  - Peripheral physeal bar resection, where cranioplast may become prominent during future growth and remodeling (TECH FIG 4)

CLOSURE

- After placement of the interposition material, cancellous bone saved during exposure is gently packed into the remaining bone cavity.
- The cortical window of bone is replaced and may be sutured in place if desired.
- Periosteum is closed over the cortical bone window.

PEARLS AND PITFALLS

<table>
<thead>
<tr>
<th>Detection</th>
<th>Absence or angulation of a Harris growth “resumption” line at the injured physis, especially when present at the contralateral physis, may be an early sign of physeal bar formation (FIG 4).</th>
</tr>
</thead>
<tbody>
<tr>
<td>Indications</td>
<td>For older patients with limited growth remaining, the surgeon should consider epiphysiodesis to prevent angular deformity or limb- or bone-length discrepancy from occurring.</td>
</tr>
</tbody>
</table>
POSTOPERATIVE CARE

- At the conclusion of the operation, local anesthetic is injected into the incision site, ketorolac (Toradol) is administered unless there is a medical contraindication, and the patient is placed in a gentle compressive dressing, which is removed on the first postoperative day.
- Patients are allowed to bear weight as tolerated with crutches as needed for comfort, and early active joint range of motion is encouraged.
- Noncontact sports are typically permitted 3 months after surgery and full-contact sports are allowed 6 months postoperatively in most patients.

OUTCOMES

- One hundred patients treated at the Mayo Clinic with physeal bar resection in the femur or tibia were followed to skeletal maturity.7
  - 13% of the patients required no additional treatment; the physeal bar was definitively treated by a single physeal bar resection procedure.
  - 94% of the patients did experience some growth after physeal arrest resection.
  - Restored physeal growth was, on average, 86% of the contralateral physeal growth rate.
  - 118 additional procedures were performed, for an average of 1.2 additional procedures per patient.
  - In all patients (except the six in whom there was no growth), any subsequent surgery was of lesser magnitude than would have been necessary had physeal bar resection not been performed.

COMPLICATIONS

- In 100 patients treated at the Mayo Clinic with physeal bar resection and cranioplast interposition followed to skeletal maturity, 2 patients had a surgical wound infection and 2 patients had a late fracture at the cranioplast site, for a total complication rate of 4%.7
- Fracture through the resection cavity after using fat as an interposition material has also been reported.2

REFERENCES

DEFINITION
- Congenital pseudarthrosis of the tibia follows pathologic fracture of a tibia.\(^2,4\)
- In most cases, the pseudarthrosis is preceded by increasing anterolateral bowing of the tibia.\(^8\)
- Spontaneous healing does not occur; shortening and angulation with instability are progressive and impair ambulation.
- Surgical treatment with a solid intramedullary rod and bone graft and long-term protection with a total-contact orthosis can provide lasting consolidation and minimize secondary deformity.\(^1,3,5,7,9\)
- Inability to achieve stable union may necessitate amputation.\(^5,7\)

ANATOMY
- The tibia is abnormal from birth; however, this may not become apparent until weight bearing begins. The remainder of the extremity is normal.
- Most patients will have anterolateral bowing that increases to the point of pathologic fracture.
- Shortening is common and tends to increase after fracture.
- As the anterior bowing increases, the foot may assume a dorsiflexed position to maintain contact with the floor.
- Involvement of the fibula is variable and may worsen as the tibial pseudarthrosis progresses.
- Nearly all cases are unilateral.

PATHOGENESIS
- Anterolateral bowing, when present, increases with weight bearing as the mechanical axis falls farther behind the axis of the tibia. Additionally, the calf musculature acts like a bowstring and increases tension within the tibia, leading to failure.
- Most pseudarthroses occur in the middle to distal third of the tibia.
- The pseudarthrosis comprises hamartomatous fibrous tissue, not neurofibroma.
- Fibular bowing or pseudarthrosis compounds the deformity and further compromises stability.\(^7,8\)

NATURAL HISTORY
- Rarely, bowing or sclerosis is present and does not progress to fracture and pseudarthrosis.
- Once established, the pseudarthrosis remains and does not resolve spontaneously. The resultant instability and shortening interferes with normal ambulation.
- Use of a total-contact orthosis may slow the progression and postpone but not eliminate the need for surgical intervention.
- More severe deformities become symptomatic at an earlier age, occasionally presenting in infancy.

PATIENT HISTORY AND PHYSICAL FINDINGS
- The most common presenting complaint is anterolateral bowing of the tibia (FIG 1).\(^2,4\) Shortening of the involved extremity may not be apparent at presentation.
- Pain is absent unless the tibia has fractured acutely.
- Limp or dull aching may precede pathologic fracture.
- Over half of these patients have neurofibromatosis (NF) type 1.\(^4,8\)
- The skin should be closely inspected for café-au-lait spots, axillary or inguinal freckles, or neurofibromas as signs of underlying NF.
- A family history of NF may be present.
- Referral to a geneticist is recommended for confirmation of the diagnosis and genetic counseling.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- Anteroposterior (AP) and lateral plane radiographs of the affected tibia are sufficient for diagnosis (FIG 2).
- The radiographic appearance of the tibia is variable; it may be cystic, sclerotic, or atrophic. There may be involvement throughout the tibia.\(^2-4\)

**FIG 1 • Standing AP photo of lower extremities. Anterior and lateral bowing is present in the left tibia of this 4-year-old girl. Shortening is minimal. The foot, knee, and thigh appear normal. Note multiple café-au-lait spots on the thighs and lateral side of the right leg, one of the major criteria of type 1 neurofibromatosis.**
SURGICAL MANAGEMENT

1. The intramedullary rod is designed to provide long-term stabilization of the tibial pseudarthrosis as the child grows. The rod remains in place, anchored by press fit in the medullary canal. The proximal tibia and the distal tibia grow away from the ends of the rod.\textsuperscript{10}

2. Younger children may require exchange with a longer rod if needed to maintain support of the tibia and stabilization of the pseudarthrosis.

Preoperative Planning

1. The dimensions of an appropriate-size rod can be determined from the plain films. The width of the medullary canal adjacent to the pseudarthrosis dictates the diameter of rod to be used. The length of the rod is determined from the lateral film.\textsuperscript{6}

2. The anticipated length of tibia to be resected to healthy bone is also measured; it is usually 1 to 2 cm.

3. In young children (less than 8 years) and in those with a very distal pseudarthrosis, the intramedullary rod should cross the ankle and subtalar joints to provide maximum stabilization because of the short distal tibial segment. The distance from the proximal tibial physis to the bottom of the calcaneus is measured. That length minus the amount to be resected is the length of intramedullary rod to be used.

4. In older children (more than 8 years), the rod can be placed within the tibia and does not need to remain across the ankle or subtalar joints. The distance from the proximal tibial physis to the distal tibial physis minus the amount of tibia to be resected is the length of rod that will be needed.

5. The Williams rod is made up of two sections: the section with the female coupling remains within the tibia and the piece with the male coupling is used as an introducer or pusher rod and is not considered in the selection of rod length (FIG 3). The rod can be cut or trimmed intraoperatively if needed to adjust the length.\textsuperscript{6}

6. If additional angular deformity is present in the tibia, an osteotomy may be needed to allow passage of the straight rod within the medullary canal.

7. If a fibular pseudarthrosis is also present, it should also be stabilized using an intramedullary Kirschner wire. If the fibula is intact, osteotomy may be needed to facilitate preparation of the tibia and introduction of the intramedullary rod.\textsuperscript{7,8}

Positioning

1. The patient is supine for preparation and rodding of the tibia. Before this, an iliac bone graft is obtained.

2. For small children, the graft should be obtained from the posterior iliac crest. In those cases, the child is positioned in the lateral decubitus position and is prepared from the waist to the toes.

3. For larger children, a bump can be placed under the buttock to facilitate positioning for an anterior iliac crest graft. It is removed before proceeding with the tibial exposure.

Approach

1. The tibia is approached directly along the anterior subcutaneous border. The incision is centered over the pseudarthrosis and extends 3 to 4 cm above and below that level.

2. The fibula is approached through a longitudinal incision, centered over the fibular pseudarthrosis, anterior to the peroneal muscles.
Chapter 33  REPAIR OF CONGENITAL PSEUDARTHROSIS OF THE TIBIA WITH THE WILLIAMS ROD

FIG 3  A. This assortment of Williams rods includes the female rod, which will remain within the tibia, and the complementary male rod used for insertion. Ideally, variable lengths and widths should be available. Selection of the appropriate-sized rod is based on the width of the medullary canal on the AP and lateral plane films. The length is estimated using the lateral film, measuring from the proximal tibial physis to the distal physis or bottom of the calcaneus, depending on the need to include the ankle and subtalar joints, and subtracting the length of the pseudarthrosis to be resected. The rod is to be coaxial with the tibia and of maximum length to minimize recurrent bowing above and below the rod as growth continues. B. Close-up view of the ends of the male and female sections. The male rod with the knurled end is the distal section and will be removed. The female flat, threaded end will be left in place. If the rod chosen is too long, it can be shortened using a bolt cutter and the tip of the rod removed, leaving the threaded end intact.

OBTAINING THE ILIAC CREST BONE GRAFT

Posterior Iliac Graft
- A 6-cm incision is made following the contour of the posterior medial corner of the iliac crest.
- The incision is carried down through the subcutaneous tissue, exposing the fascia overlying the iliac crest and abductor musculature.
- The apophyseal cartilage is exposed along the ilium and is split in half, sharply, along the course of the iliac crest.
- The lateral (superficial) half of the apophyseal cartilage and attached periosteum is elevated to expose the outer table of the ilium, subperiosteally.
- An osteotome is used to cut the outer table. Cortical and cancellous strips are obtained.
- The apophysis is reapproximated with interrupted sutures. A drain is used at the surgeon’s discretion. The subcutaneous layer and skin are closed, and the patient is then rolled to the supine position.

Anterior Iliac Crest Graft
- In larger children, the anterior iliac crest can be used.
- The approach is similar except the incision is centered over the anterolateral ilium.

PREPARATION OF THE TIBIA

- A sterile thigh tourniquet is applied and inflated.
- A 6- to 8-cm longitudinal incision is made over the tibial pseudarthrosis, along the subcutaneous border.
- The tibia is exposed subperiosteally and circumferentially around the pseudarthrosis.
  - The plane for subperiosteal dissection is more readily identified proximal and distal to the pseudarthrosis rather than directly over it.
  - The fibrous tissue within the pseudarthrosis is removed to expose the bone. A combination of sharp dissection, rongeur, and curettage is used.
  - The pseudarthrosis must be excised in addition to the abnormal dense, sclerotic bone adjacent to it.
  - The medullary canal can be probed and identified with a small curette.
  - A drill bit, smaller in diameter than the intramedullary rod to be inserted, is used to open and enlarge the medullary canal above and below the pseudarthrosis (TECH FIG 1A).
- The C-arm image is used to ensure that the canal preparation is not eccentric.
- If secondary bowing is present, it may not be possible to remain within the central medullary canal. Osteotomy of the tibia at that level should allow passage of the drill bit, remaining central in the medullary canal.
- Distally, the drill bit is passed through the tibia, stopping at the physis.
- If the rod will be left across the ankle and subtalar joints, a similar-sized smooth Kirschner wire is used to perforate the talus and calcaneus. Care must be taken to hold the foot and ankle in a neutral position during this process.
- Preparation of the tibia is complete when the drill bit can be passed through the proximal fragment up to the physis and distally to the physis.
- The drill bit should be centered within the tibia in both the AP and lateral images (TECH FIG 1B).
A fibular pseudarthrosis is approached through a lateral incision, anterior to the peroneals. The fibula is exposed subperiosteally and the fibrous tissue and adjacent pathologic bone are removed, as in the tibia.

- Care must be taken to avoid injury to the deep motor branches of the peroneal nerve, just medial to the fibula.
- Ideally, the fibula is stabilized with an intramedullary Kirschner wire. This is inserted through the distal fragment, exiting the skin at the tip of the fibula. After insertion of the tibial rod, the wire is then drilled into the proximal fibula. In some cases this cannot be accomplished because the fibula is too atrophic.
- An intact fibula may interfere with preparation of the tibia as it can limit mobilization of the proximal and distal fragments. It can also prevent contact of the tibial fragments. Osteotomy of the fibula will resolve the issue. It may be necessary to resect a portion to allow compression across the tibia.

TECH FIG 1 • Preparation of the tibia. A. A drill bit is used to open the medullary canal proximal and distal to the pseudarthrosis. C-arm image intensification is used to maintain central positioning within the medullary canal on the AP and lateral views. If there is severe bowing of the tibia, an osteotomy may be needed to prevent eccentric reaming, as in this patient. B. Lateral C-arm image of the distal tibia showing central position of the drill bit, stopping just above the distal phys. A similar-size Kirschner wire can be used to cross the physis, talus, and calcaneus if needed prior to rod insertion.

PREPARATION OF THE FIBULA

- The length of the rod is checked before insertion by reducing the tibia, laying the rod next to the leg, and noting the position of the rod proximally and distally.
  - The proximal point should be just below the proximal tibial physis.
  - The flat, distal end (female) should be at the distal tibial physis (if the rod is to remain within the tibia) or within the calcaneus (if the rod will stabilize the ankle and subtalar joints).
  - If the rod is too long, the pointed end can be cut on an angle to the appropriate length.
  - The rod sections are assembled by twisting the two sections together. A power drill is used to insert the pusher section into the distal fragment and it is advanced antegrade, across the ankle and subtalar joints, exiting the bottom of the foot through the heelpad (TECH FIG 2A).
  - The foot must be kept in a neutral position both in plantarflexion and dorsiflexion as well as varus-valgus alignment.
  - A small incision may be needed to relieve the skin tension around the rod (TECH FIG 2B).
  - The drill is detached from the proximal rod section and reattached to the distal rod, exiting the foot. The rod is drawn into the distal fragment (TECH FIG 2C).

STABILIZATION WITH THE WILLIAMS ROD

- The tibia is reduced and the rod advanced retrograde across the pseudarthrosis into the proximal tibia, stopping adjacent to the tibial physis (TECH FIG 2D,E).
- C-arm imaging is used to ensure concentric location of the rod within the tibia (TECH FIG 2F,G).
- The rod is grasped through the pseudarthrosis; with the drill on reverse, the pusher rod will disengage the female section (TECH FIG 2H). Spot C-arm images are used to confirm satisfactory position of the rod before the pusher is completely removed.
- Contact of the tibial fragments is confirmed visually. If the fragments are distracted, the surgeon should osteotomize or remove more fibula to ensure contact is made.
- The fibular Kirschner wire is advanced into the proximal fibula and cut flush with the tip of the fibula.
- The bone graft is placed circumferentially about the tibia (TECH FIG 2I). Cortical strips can be secured with loops of suture placed around the tibia. Cancellous bone is placed within and across the pseudarthrosis.
- The tourniquet is deflated and circulation assessed around the repair and in the foot.
- The periosteum usually cannot be closed over the bone graft. The wound is closed in layers over a drain.
TECH FIG 2 • A. The male section of the Williams rod is inserted antegrade into the distal segment and advanced through the talus and calcaneus. The foot must be held in neutral flexion and mediolateral angulation as the rod is passed. B. The Williams rod is pushed through the heelpad as it exits the foot. A small incision may be needed to relieve the skin tension around the rod. C. The Williams rod is assembled by twisting the male and female sections together. The drill is attached to the exposed tip of the male section and the rod is drawn into the distal fragment. Note the neutral position of the foot relative to the tibia. D,E. The tibial fragments are approximated and the rod is advanced retrograde into the proximal tibia. F. As the rod is advanced, C-arm images are used to confirm satisfactory coaxial positioning of the rod in both planes. This AP view shows satisfactory position. The rod fills the middle of the canal. A fibular shortening osteotomy has also been completed to allow contact of the tibial fragments. This is usually necessary to avoid distraction by an intact fibula after resection of the pseudarthrosis. G. Lateral C-arm image of the advancing rod. The rod is slightly anterior and can be withdrawn and redirected posteriorly to achieve a satisfactory position. In the presence of more severe bowing, an osteotomy would be needed to achieve satisfactory alignment. H. Once the rod is in satisfactory position within the proximal tibia, the male section is partially untwisted from the female section. It may be necessary to grasp the rod through the pseudarthrosis to disengage the two sections. The lateral C-arm image reveals the position of the distal end of the rod before the sections are completely disengaged. The separation of the sections is shown at the arrow. The proximal–distal position of the rod can easily be adjusted if needed. Once contact of the tibial fragments is also confirmed by direct vision and C-arm, the male end is detached and removed. I. The medullary canal is packed with cancellous bone. The corticocancellous strips are placed circumferentially about the pseudarthrosis. These can be secured by loops of suture passed around the tibia.
PEARLS AND PITFALLS

<table>
<thead>
<tr>
<th>Patient selection</th>
<th>▪ This procedure should be considered only for patients with an established pseudarthrosis. Infants and young children with anterolateral bowing (prepseudarthrosis) should be observed and treated with a total-contact orthosis.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Alignment and centering of the rod</td>
<td>▪ Residual anterior angulation increases the potential for recurrent bowing and refracture. Placement of the rod in a colinear fashion within the tibia—that is, a straight rod within a straight tibia—optimizes protection of the tibia from deformity and fracture. As the tibia grows away from the ends of the rod, bowing may increase through this unprotected segment.</td>
</tr>
<tr>
<td>Foot position</td>
<td>▪ If the ankle and subtalar joints are transfixed by the rod, it is important to maintain neutral alignment and a plantigrade foot. Because of the anterior bow, the foot tends to assume a dorsiflexed position; the lateral bow promotes a valgus deformity at the ankle. A calcaneus foot position further weakens the posterior musculature of the leg. Angular deformity may require treatment by hemiepiphyseodesis or guided growth.</td>
</tr>
<tr>
<td>Distraction</td>
<td>▪ An intact or overly long fibula may distract the tibia and compromise consolidation. Osteotomy with shortening as needed to permit contact of the tibial fragments resolves the issue.</td>
</tr>
<tr>
<td>Rod selection</td>
<td>▪ Ideally the rod spans enough of the tibia to provide long-term mechanical support and protection of the pseudarthrosis. As growth occurs, more of the tibia is exposed to stresses that promote recurrence of bowing. Selection of the longest and greatest-diameter rod is best. Preoperative measurements from plain films provide a reliable guide for the length and width needed. An assortment of rod sizes are available and may need to be modified—that is, cut to an appropriate length—before surgery.</td>
</tr>
<tr>
<td>Orthotic management</td>
<td>▪ Use of a total-contact orthosis is essential throughout growth to reduce stress through the pseudarthrosis and maintain consolidation. A solid AFO is used if the rod transfixes the ankle and subtalar joints. A KAFO is used in young children (less than 5 years).</td>
</tr>
</tbody>
</table>

**POSTOPERATIVE CARE**

- Cast immobilization is used postoperatively until consolidation of the pseudarthrosis occurs, usually at least 12 weeks. A one-and-a-half spica cast is used for infants and young children (less than 6 years) to minimize stress across the pseudarthrosis. A long-leg, non-weight-bearing cast is used in older children.

- A total-contact orthosis is used long term to protect the area of consolidation and reduce mechanical stresses on the lower leg that promote anterior bowing. Initially a nonarticulated KAFO is used in young children and in those with the rod across the ankle and subtalar joints. This is changed to an articulated AFO when the rod is positioned within the tibia, no longer transfixing the ankle.

**FIG 4 • A.** AP view of tibia after rodding in this 5.5-year-old girl shows ideal rod placement centrally within the tibia. The proximal tip of the rod is just below the physis, the fragments are in contact, and the distal rod is central within the tibia and also fills the medullary canal. The ankle is in neutral varus–valgus alignment. The fibula is very atrophic and could not be stabilized even with a small-diameter Kirschner wire. **B.** Lateral view of the same patient. The rod crosses the ankle, which is held in neutral flexion. The rod controls a maximum length of the tibia and centers the proximal tibia over the plafond.
Once the ankle is no longer transfixed, an ankle rehabilitation program is implemented that includes range of motion and calf strengthening.

Periodic follow-up is necessary throughout growth to monitor the quality of healing and maintenance of good rod position (FIG 5).

Ambulation and activities are unrestricted as long as the orthosis is used. Once skeletal maturity is reached, the orthotic use is recommended for sports and high-stress activities.

OUTCOMES

Patients resume independent ambulation with long-term orthotic protection.

Consolidation reliably occurs in 90% of cases with this technique.1,3,5,7-9

Two long-term studies assessed the quality of maintenance of healing, with variable results. Both studies emphasized the importance of paying attention to details regarding the technique of rod insertion, continued orthotic use, and long-term follow-up care.7,8

Anterior bowing may recur and lead to refracture. If the rod is in good position, healing can be obtained by simple cast immobilization. If healing is delayed, the addition of bone graft will generally lead to union.1

Valgus angulation may also occur and may need to be managed by guided growth or hemiepiphysiodisis.8

Limb-length inequality is variable. It is more common with patients with severe deformity, those requiring greater length of pseudarthrosis resection, and those with recurrent fracture.

While most patients realized long-term satisfactory healing and function, some patients ultimately chose amputation after multiple recurrent fractures resulting in loss of function or limb-length inequality.7,8

COMPLICATIONS

Complications include those routinely associated with musculoskeletal procedures, such as swelling, wound healing, and pain, with similar incidence.

The most likely intraoperative complication is neurovascular injury, particularly to the deep motor branches of the peroneal nerve. These are at risk during fibular osteotomy.

None of the studies have reported occurrence of a compartment syndrome, although this could be produced by overzealous use of bone graft, which may compress the tibial vessels. Fasciotomy is usually incidental with the surgical approach to the tibia.

Refracture with progressive shortening and loss of stability may compromise function sufficiently to warrant amputation.

Satisfying the primary goal of a healed pseudarthrosis is easier to accomplish than maintaining union, which serves to emphasize the recalcitrant nature of this pathologic process.

REFERENCES

**DEFINITION**

- Limb lengthening is a surgical procedure performed to lengthen a bone.
- In the Ilizarov method, lengthening is accomplished by gradual bone distraction through a low-energy, atraumatic corticotomy site. The bone fragments are controlled via stable bone fixation using half-pins and tensioned wires through bone that are rigidly fixed to an external ring fixator or arch.\(^1\)\(^1\)
- When a monoplanar fixator is used, lengthening is accomplished by distraction of the atraumatic corticotomy of the bone.\(^9\)\(^,\)\(^18\)

**ANATOMY**

- Using the Ilizarov method, one can lengthen bones of both the upper and lower extremities, including bones of the hand and foot and the surrounding soft tissue.
- The most commonly lengthened bones in the lower extremity include the tibia and fibula, the femur, and the metatarsal. In the upper extremity, the most commonly lengthened bones are the humerus, the radius and ulna, and the metacarpal bones.
- Consideration is given to lengthening of the surrounding soft tissues, which include the muscle tendon unit, neurovascular bundle, and skin.\(^11\)
- During bone lengthening, the tension in the surrounding soft tissue may predispose the lengthened segment to deformity\(^12\),\(^19\):
  - Femur: varus and procurvatum
  - Tibia: valgus and procurvatum
  - Humerus: varus and procurvatum
  - Radius and ulna: has a tendency to collapse in the interosseous space, which may cause synostosis
  - Metatarsal and metacarpal: apex dorsal angulation
- During large lengthening, care is necessary to prevent subluxation or dislocation of the adjacent joint.\(^19\)
- Femoral lengthening, especially in the setting of congenital short femur, may result in hip or knee subluxation or dislocation secondary to associated deficient acetabular coverage at the hip and the high frequency of deficient cruciate ligaments at the knee.
- Tibial lengthening may cause knee or ankle subluxation and progressive equinus deformity of the foot.
- Metatarsal and metacarpal lengthening can cause metatarsophalangeal subluxation.
- All of these issues are considered during any lengthening procedure.

**PATHOGENESIS**

- The term *distraction osteogenesis* implies synthesis of new bone by slow, gradual (no more than 1 mm per 24 hours) controlled distraction of the bone fragments under conditions of rigid fixation.\(^7\)\(^,\)\(^11\)
  - The new bone is formed mostly by intramembranous ossification and, to a lesser extent, through endochondral ossification.\(^9\)\(^,\)\(^11\)
  - To provide maximum construct stability and to minimize soft tissue trauma, it is important to maintain the two fragments well apposed to each other following the corticotomy.
  - Distraction is a good tool for influencing reparative regeneration of both the bone and the soft tissue (“stretching tension,” as described by Ilizarov). However, the new regenerate ossifies and remodels slowly.
  - Gradually removing distraction and applying mild compression increases the rate of remodeling. Therefore, the regenerate becomes more rigid against bending loads.
  - To prevent any shortening of the segment from compression, preliminary over-distraction of up to 0.5 to 1 cm may be performed.
  - Functional load is a strong stimulus for the improvement of blood flow and allows organic remodeling of the regenerated osseous part. The extent of load depends on the stability of fragments and the amount of regenerate.

**NATURAL HISTORY**

- The natural history of the limb-length discrepancy (LLD) depends on the condition causing the LLD.\(^16\),\(^22\) A partial list of causes follows:
  - Congenital shortening: Proximal focal femoral deficiency, coxa vara, congenital short femur, fibula and tibia hemimelias, hemiatrophy
  - Congenital lengthening: Overgrowth syndromes such as hemihypertrophy, Beckwith-Weidemann syndrome, Klippel-Trenaunay-Weber syndrome, and Parke-Weber syndrome
  - Skeletal dysplasia or tumor: Multiple hereditary exostoses may result in limb shortening on the affected side as growth cartilage cells are diverted to the cartilage tumor.\(^18\) Radiation for malignancies adjacent to the physes may result in growth suppression or complete destruction of physese cartilage cells, resulting in limb-length discrepancy or angular deformity.
  - Infection: Physial destruction may result from physial invasion from adjacent metaphyseal or epiphyseal bacterial osteomyelitis, or direct physial involvement in the case of intracapsular joint physis such as at the hip and shoulder.
  - Paralysis: Poliomyelitis and cerebral palsy as well as other nervous system afflictions in children typically result in shortening on the more affected side.
  - Trauma: Direct injury to growth plate, postraumatic bone loss or shortening, and overgrowth following femoral fracture
  - Miscellaneous: Slipped capital femoral epiphysis, Legg-Calvé-Perthes disease
  - Upper extremity discrepancy or shortening usually does not cause major functional problems, but may result in significant cosmetic deformities.
Predicted lower extremity discrepancy of 3 to 5 cm may be dealt with by long-leg epiphysiodesis in children or by leg lengthening using the Ilizarov technique. LLD greater than 5 cm is amenable to leg lengthening.\(^{22}\)

In children, the LLD at maturity can be predicted in a variety of ways:
- The arithmetic method\(^{13}\)
- The growth remaining method\(^{1}\)
- The Moseley straight line method\(^{15}\)
- The Paley multiplier technique\(^{20}\)

Untreated LLD of more than 3 cm may result in pelvic obliquity, visual gait disturbance, short-legged gait, or structural/nonstructural scoliosis.\(^{22}\)

LLD greater than 5.5% of the long leg has been shown to decrease the efficiency of gait, as determined from kinetic data.\(^{21}\)

**PATIENT HISTORY AND PHYSICAL FINDINGS**

- The common symptoms at presentation are limp, compensatory gait mechanics, pelvic obliquity, and nonstructural scoliosis.
- Physical findings depend on the etiologic factors.\(^{22}\)
- In hemihyperplasia (both syndromic and nonsyndromic), the affected extremity may be larger in both length and girth. In classic hemihyperplasia, upper extremity hypertrophy as well as hemifacial asymmetry may be present. Vascular overgrowth syndromes may be associated with cutaneous or deep hemangiomas, which may alter surgical approaches to attempted limb equalization.
- Clinically, LLD is best measured by the block test, in which the shorter leg is placed on increasingly larger measured blocks until the posterior iliac crest is level. Discrepancies as small as 2 cm are accurately detected by this method, and detection of discrepancies is largely unaffected by patient size or body mass. Direct measurement of leg length from anterosuperior iliac spine to the tip of medial or lateral malleolus is significantly less accurate.
- Apparent leg length is measured with the patient supine with the legs parallel to each other. The landmarks are the umbilicus to the tip of medial malleolus. Pelvic obliquity and fixed deformities of the hip and knee affect the reading.
- True leg length is measured from the anterior superior iliac spine to the tip of the medial malleolus. It is important to place the legs in identical positions to measure true leg length.
- If the patient has a 20-degree abduction deformity of right hip, the left hip is placed in 20 degrees of abduction to measure true length.\(^{22}\)
- Range of motion is noted for all joints, primarily the hip, knee, ankle, and subtalar joints. The ankle joint range of motion is measured with the knee in extension and flexion.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Plain radiographs are helpful to document the objective measurement of LLD (FIG 1).
- Full-length (hip to ankle) anteroposterior (AP) radiographs are obtained in standing position with both patellae facing directly anteriorly. The appropriate-sized block is placed beneath the shorter leg to level the pelvis. A long x-ray cassette (51-inch) is used with the x-ray beam centered focused on the knee from a distance of 10 feet. A radiolucent ruler often is used to assist in calculation of limb discrepancies.

**DIFFERENTIAL DIAGNOSIS**

- True shortening (eg, femoral or tibial)
- Apparent shortening due to dislocated hip
- Apparent shortening from contractures
- Angular deformity causing apparent shortening
- Overgrowth syndrome with both increased length and limb girth: hemihypertrophy
- Congenital limb deficiency (beware knee joint instability)

**NONOPERATIVE MANAGEMENT**

Nonoperative management is based on the amount of discrepancy:\(^{16}\):
- 0 to 2 cm: no treatment
- 2 to 6 cm: shoe lift (option for epiphysiodesis or lengthening in this range)
- More than 20 cm: extension prosthesis

**SURGICAL MANAGEMENT**

*Preoperative Planning*

**Ilizarov Method**

- Accurate radiographic measurement of current discrepancy and calculation of projected LLD at maturity
- Determination of which bony segment is affected
- Assessment of compensatory mechanics used for walking: equinus gait, circumduction, vaulting, or combination\(^{21}\)
- Assessment of contractures: eg, extra- or intra-articular, bony
- Assessment of associated deformities: eg, angulation, translation, and rotation
- Long-leg standing radiographs in both planes help determine malalignment.
Stability or laxity of joints (hip, knee, ankle) is determined clinically and radiographically.

- Skin condition: eg, open defect, scar tissue
- Planning for corticotomy level, for lengthening as well as for correction of associated deformity with appropriate room for wire or half-pin fixation.
- Determine optimum frame configuration, with or without inclusion of the adjacent joint.
- Details on ring size, half-pin, or K-wire placement
- Single-stage lengthening of 10% to 15% of bone length is associated with fewer complications.

Technical considerations
- The Ilizarov frame may be constructed before surgery. The design of the frame and the number of rings and arches depend on the amount of lengthening planned.
- Separate threaded connecting rods are used between each ring block and the next. A rod spanning two or more rings allows less flexibility if adjustments are needed.
- Adequate skin clearance of at least 2 to 3 cm must be maintained circumferentially under the ring. Small rings are more rigid than large rings, but smaller rings may hinder skin care and may cause soft tissue compression if there is postoperative swelling.
- A template or an actual ring can be used to select the appropriate ring size (Fig 2).
- Due to the changing diameter of each limb segment, different ring sizes may be required for a single limb segment (for example, the diameter of the proximal arch for the femur typically is larger than the distal ring).

Monoplanar Fixation
- True measures of current discrepancy and calculation of projected LLD
- Compensation mechanisms used during walking: equinus gait, circumduction, vaulting
- Assessment of contractures: extra- or intra-articular
- Associated deformity: angulation, translation, and rotation
- Stability or laxity of joints: eg, hip, knee, ankle
- Skin condition: eg, open defect, scar tissue
- Long-leg films showing hip, knee, and ankle for lower extremity; and similar long films for the upper extremity
- Planning for corticotomy level; osteotomy level if needed for correction of associated deformity; and planning for points of fixation
- Choose appropriate size arch, rods, rail, half-pin and/or K-wires.

Choose the appropriate size of the fixator (pediatric or adult)

Positioning
- Lower extremity: Supine position on any radiolucent table (eg, Jackson table)
- Upper extremity: Supine position with arm over a radiolucent table
- Intraoperative fluoroscopy (for both the AP and lateral images)
- For the Ilizarov method:
  - Place rolled sheets (as bumps) beneath the ipsilateral buttock and proximal tibia, leaving the femur free (Fig 3A).
  - Similarly, for the tibia, a rolled sheet is placed beneath distal femur and ankle to create space for the tibial frame (Fig 3B).
  - Place a sandbag beneath the ipsilateral shoulder/scapula and rolled sheets (as bump) beneath the humerus and radius ulna to create a space for the frame.
- For monoplanar fixator use, place rolled sheet (as bumps) beneath the femur and tibia to create working space for application of the frame.

Monoplanar Fixation
- True measures of current discrepancy and calculation of projected LLD
- Compensation mechanisms used during walking: equinus gait, circumduction, vaulting
- Assessment of contractures: extra- or intra-articular
- Associated deformity: angulation, translation, and rotation
- Stability or laxity of joints: eg, hip, knee, ankle
- Skin condition: eg, open defect, scar tissue
- Long-leg films showing hip, knee, and ankle for lower extremity; and similar long films for the upper extremity
- Planning for corticotomy level; osteotomy level if needed for correction of associated deformity; and planning for points of fixation
- Choose appropriate size arch, rods, rail, half-pin and/or K-wires.
**Tibial Lengthening**

**Wire Insertion**
- The wire insertion site is determined by local anatomy and the use of cross-sectional anatomic atlases to protect and avoid damage to blood vessels, nerves, and tendons.
- In small children, 1.5-mm fixation wires are used; in adolescents and adults, 1.8-mm fixation wires are used. The wires usually are tensioned to 100 kg in children and to 130 kg in adults.
- The wire is introduced from the side nearest the neurovascular bundle. This helps prevent inadvertent injury to the neurovascular structures.
- Initially the wire is gently pushed through the soft tissue until it hits bone cortex. The center of the bone is located, and the wire is drilled through the cortex. It is important not to bend the wire while drilling.
- The wire is prevented from bending by a short lever arm on the wire that holds the wire with a wet sponge or by use of a protective soft tissue sleeve (TECH FIG 1).
- After piercing the far cortex, the lowest possible drill speed is used to further insert the wire. After exiting the far skin, the wire is inserted further by tapping with a mallet.
- The wire is fixed to the ring without bending the wire. Bent wires will move the bony fragments on tensioning.
- Any tension or puckering of the skin at wire insertion or exit is corrected by releasing the surrounding skin or fascia with the help of a no. 15 blade on a scalpel.

**Half-Pin Insertion**
- Hydroxyapatite-coated half-pins are recommended, because they achieve better fixation and are associated with lower rates of infection and loosening.\(^3\)
- The size of the half-pin should not exceed one-third the diameter of the bone segment being fixed.
- Freehand technique
  - Identify the optimal site for pin insertion.
- Incise the skin over the insertion site, and then dissect down to the bone using a hemostat.
- Now drill the bone (both cortices) through a protective drill sleeve.
- The half-pin is introduced in the drilled track. The pin traverses only 1 to 2 mm through the far cortex, confirmed with fluoroscope.
- The half-pin is attached to the ring or arch, which is positioned perpendicular to the bone segment.
- If the half-pin insertion is not perpendicular to the bone, a post and half-pin fixation bolt are utilized.
- Ring guide technique
  - First the ring or arch is fixed perpendicular to the bone with a wire.
  - Depending on the optimal site for pin insertion, the half-pin fixation bolt or Rancho cube is attached to the ring.
  - Now the sleeve is introduced through the half-pin fixation bolt or cube, and the skin site is marked.
  - The skin is incised and dissected to the bone using a hemostat.
  - The sleeve is advanced further to contact the bone.
  - The drill is introduced through the sleeve, and the bone is drilled (both cortices).
  - The half-pin is introduced in the drilled track. The pin traverses 1 to 2 mm through the far cortex, and this is confirmed fluoroscopically.
  - The half-pin fixation bolt or the cube is tightened over the pin.

**Fibular Osteotomy and Anterior Compartment Fasciectomy**
- The osteotomy is done at the junction of the proximal and middle thirds of the fibula. Avoid osteotomies of both the tibia and fibula at same level.
- The fibula is approached laterally through the plane between the peroneus longus and the lateral intermus-
cular septum. The periosteum is incised with a sharp knife and is elevated circumferentially with a periostal elevator.

- A Hohmann or Bennett retractor then is placed around the exposed fibula to protect the surrounding soft tissue.
- The fibula is osteotomized, either with an oscillating saw or using an osteotome, after placing several drill holes through both cortices. Irrigation fluid is used to prevent thermal necrosis while using the saw or drill.
- An oblique osteotomy is used to have larger contact area between the two fragments.
- The skin and subcutaneous tissues are closed without closing the underlying fascia.
- Now the skin is incised over the tibial corticotomy site. The corticotomy site usually is the proximal metaphysis.
- Prophylactic fasciotomy of the anterior compartment may be performed by releasing the anterior compartment fascia distally and proximally with a Metzenbaum scissors.
- We recommend fasciotomy before the frame is mounted, because more space is available to work. However it can be done later after mounting the frame.
- Now a temporary suture is placed over the proximal tibial incision, deferring the corticotomy until later in the procedure.

Ilizarov Frame Application

- For simple lengthening (without deformity), three rings (or two rings and one arch) are used.
- Introduce a transverse proximal tibial wire perpendicular to the shaft and below the growth plate in children (TECH FIG 2, #1).
- To avoid penetrating the joint capsule, the transverse wire should be no closer than 14 mm to the subchondral bone of the proximal tibia.
- Attach the proximal ring (previously constructed frame) to this wire, and tension the wire with a wire tensioner. Adequate ring clearance from the soft tissues must be verified circumferentially.
- Another transverse wire is introduced in the distal metaphysis of the tibia proximal to the distal growth plate and fixed to the distal ring (TECH FIG 2, #2).
- The biomechanical and anatomic axis of the tibia is the same in the absence of deformity.
- The lengthening rods are placed parallel to the biomechanical axis. Radiographically, the rods should be parallel to the posterior cortex on the lateral view and parallel to the longitudinal axis of the tibia on the AP view.
- Next a wire is placed proximally, passing from lateral to medial. This wire enters the fibular head (just distal to the proximal fibular growth plate), traversing the tibia and exiting through the anteromedial tibial cortex.
  - Care is necessary to prevent damage to the peroneal nerve, which is in close proximity to the fibular neck.
  - The wire is then fixed and tensioned to the proximal ring.
- Now two half-pins are placed in the most proximal ring. In this configuration, there should ideally be 90 degrees of angulation between the two pins (TECH FIG 2, #3).
- Usually a half-pin fixation bolt is required with one half-pin and a one-hole cube for the other half-pin, so that the pins are placed at slightly different levels.
- It is important not to damage the tibial tubercle and proximal tibial physis while placing the half-pins or wires.
- Next, a wire is placed distally through the fibula and tibia just above the growth plate at the level of the syndesmosis (TECH FIG 2, #4). This wire is attached and tensioned to the distal ring.
- Place the fibula-tibia wire more than 12.2 mm from the distal tibia subchondral surface to avoid capsular penetration and the risk of joint sepsis.
- A half-pin is introduced just proximal to the distal ring in an anteromedial direction. It is then fixed to the distal ring (TECH FIG 2, #5).
- One or two half-pins are similarly introduced just above and below the middle ring and are securely fixed to the middle ring (TECH FIG 2, #6).
- The connecting rods between the proximal and middle rings are then disconnected, and attention is directed to the corticotomy site.
- Extra-periosteal dissection is performed at the proximal tibial metaphyseal osteotomy site.

![TECH FIG 2](image)

**TECH FIG 2** The sequence and placement of K-wires or half-pins in tibial lengthening. 1, Proximal transverse tibial wire perpendicular to the shaft and below the growth plate in children. This wire is placed anterior to the fibula head. 2, Transverse wire in the distal metaphysis of the tibia proximal to the distal growth plate. 3, Two half-pins are inserted proximally, one above and one below the proximal ring at an approximate angle of 90 degrees to one another. 4, Distal wire through the fibula and tibia above the growth plate at level of syndesmosis. 5, Distal tibial half-pin is introduced in the anteromedial direction. 6, One or two half-pins are introduced, just above and below the middle ring.
The periosteum is not elevated circumferentially, in order to preserve the blood supply.

**Corticotomy**

- Multiple drill holes are made in both tibial cortices from anterior to posterior. If necessary, additional drill holes can be made at the same level from another point over the anteromedial cortex (TECH FIG 3A).
- A 5-mm osteotome is advanced through the bone at the level of the drill holes (TECH FIG 3B).
- First the anteromedial cortex is osteotomized, followed by the anterolateral cortex. Each time the osteotome passes through the far cortex, it is twisted with a wrench to cause a controlled fracture in the cortex.
- Finally, a wider osteotome is seated in the posterior cortex and twisted with a 14-mm wrench to break the posterior cortex.
- The corticotomy is confirmed by externally rotating the distal block. Internal rotation is avoided, because it places tension on the common peroneal nerve. The fragments are rotated back to the normal reduced position.
- The rods between the proximal and distal blocks are reconnected as they were before the corticotomy, and the osteotome is reduced.
- The use of square nuts or clickers on the connecting rods allows future distraction.

**Wound Closure**

- The skin is closed without closing the underlying fascia.
- Check that all the nuts and bolts are tight.
- Put a dressing (eg, Xeroform [Covidien, Mansfield, MA], sponges) around the wires and half-pins. Pressure dressing is applied over the fibular and tibial corticotomy sites. Place the dressing material between the frame and the surgical wound.

The foot is placed in a plantigrade position and a footplate is attached. When planning a large lengthening, the foot may be included in the frame to prevent progressive equinus deformity of the ankle.

Similar consideration is given to including the knee in the frame for large lengthening or in the setting of cruciate ligament laxity.

**Taylor Spatial Frame**

- The Taylor Spatial Frame (TSF; Smith & Nephew, Andover, MA) has Web-based spatial software, which helps to calculate correction of deformity or lengthening of the bone.
- Deformities can be corrected using chronic deformity correction, the rings-first method, or the residual deformity method.
- In the TSF, the proximal and distal blocks may or may not be connected preoperatively.
- The number and site of wire/half-pin fixation, the number of rings, and the basic construct of the frame are similar to those described earlier.
- The details of fibular osteotomy and anterior compartment fasciotomy are the same.
- Mount the frame and secure with wires and half-pins.
- The proximal and distal blocks are connected with six connecting struts. The details of the strut lengths are recorded, after which the struts are disconnected and corticotomy is completed as discussed earlier.
- The corticotomy is reduced, and the struts are reconnected the way they were before the corticotomy (TECH FIG 4).
- The deformity, frame, and mounting parameters are entered in the software program, which prescribes a lengthening/corrective program.
- The rate of distraction is determined based on local bone and soft tissue status. Typically, it is 1 mm per day in healthy bone and soft tissue.
Femoral Lengthening

- The usual frame construct for simple femoral lengthening (without deformity) is composed of two rings and one arch.
- Initially, a transverse wire is placed in the distal femur, parallel to the knee joint line and proximal to the growth plate in children (TECH FIG 5A, wire 1). The direction of the wire is from lateral to medial.
- The previously constructed frame is mounted, and the distal ring is attached to this wire. The wire is then tensioned. All the rings, including the arch, should have at least one or two fingerbreadths clearance from the anterior and posterior surface of the thigh.
- The mechanical and anatomic axes of the femur are not identical as in the tibia. The mechanical axis is drawn from the center of the femoral head to the center of the knee joint, whereas the anatomic axis is the central axis of the femoral shaft. The anatomic axis forms a 7-degree angle with the mechanical axis.
- A transverse half-pin is introduced in the lateral proximal femur perpendicular to the mechanical axis, using the ring guide technique (TECH FIG 5A, pin 2). The pin is placed centrally in the lateral cortex and is fixed to the proximal arch.
- The frame rods are placed parallel to the mechanical axis. Radiographically, the rods are parallel to the posterior cortex on the lateral view and parallel to the mechanical axis (marker from center of femoral head to the center of knee joint) on the AP view.
- Next, two half-pins are placed in the distal femur proximal to the growth plate. The direction of these half-pins is from posterolateral to anteromedial and from posteromedial to anterolateral (TECH FIG 5A, pin 3).
- While introducing half-pins, it is necessary to flex the knee to avoid placement across the tendon and muscle (ie, biceps femoris, semitendinosus, semimembranosus). Care is necessary to prevent any damage to the common peroneal nerve, which is in close relationship with the biceps femoris.
- One or two half-pins are introduced in the proximal femur (TECH FIG 5A, pin 4). The half-pins are fixed to the proximal arch using different-size Rancho cubes to avoid pin placement at the same level.
- Next, one or two half-pins are placed adjacent to the middle ring (TECH FIG 5A, pin 5).
- The rods between the middle and distal rings are disconnected for corticotomy of the distal femoral metaphysis.
- A skin incision is made over the anterolateral distal femur close to the distal metaphysis. The deep tissue is incised, and the vastus lateralis is elevated by blunt dissection to expose the lateral femoral cortex without disturbing the underlying periosteum. The osteotomy is performed approximately 1 cm proximal to the most proximal wire or half-pin attached to the distal ring.
- The cortex is drilled at the same level, with multiple drill holes at varying angles. A 5-mm osteotome is advanced through the anterior, lateral, medial, and posterior cortices.
- Each time the osteotome is fully seated through the far cortex it is twisted with a wrench to cause an atraumatic fracture in the cortex. The corticotomy is confirmed by externally rotating the distal ring.
- The fragments are rotated back to the normal reduced position. This will decrease bleeding from the cut bony surfaces.
- The rods are reconnected as before the corticotomy. Square nuts or clickers are used with these connecting rods to allow for controlled distraction.
- The corticotomy site is closed. A check is done to tighten all nuts and bolts (TECH FIG 5B).
During large lengthening and in presence of knee ligament laxity, one should consider extending the frame across the knee joint.

**Taylor Spatial Frame**
- When using the TSF for femoral lengthening, the proximal and distal blocks may or may not be connected preoperatively.
- The number and site of wire/half-pin fixation, number of rings, and basic construct of the frame are similar to those described with the ilizarov technique.
- Mount the frame and secure with wires and half-pins.
- The proximal and distal blocks are connected with six connecting struts. The details of the strut lengths are noted. Then the struts are disconnected and corticotomy is completed as discussed earlier.
- The corticotomy is reduced, and the struts are reconnected at the same lengths as before corticotomy (TECH FIG 6). This results in anatomic reduction at the osteotomy site.
- The deformity, frame, and mounting parameters are entered in the software program, which prescribes a lengthening/deformity correction program. Lengthening proceeds at 1 mm/day under normal circumstances.

**MONOPLANAR FIXATOR ASSEMBLY**

**Technical Considerations**
- Monolateral fixators stabilize bone fragments using percutaneous half-pins to transfix the bone with external fixation of the half-pin to the clamp, rail, rod, or arch.
- Some monoplanar systems use arches or rings to achieve multiplanar fixation.
- Advantages of monoplanar fixators:
  - Greater patient comfort during femur and humerus lengthening
  - Less bulky frame
  - Simple construct

- Disadvantages of monoplanar fixators:
  - Less rigid
  - Less flexible: eg, the MAC frame (EBI, Parsippany, NJ) has a universal hinge that allows correction of angular deformity and a translation device that allows correction of translation in two directions.
  - Not recommended for large lengthening (more than 5 cm)
- The monolateral frame is constructed before the surgery is done. The design of the frame, including the number of clamps and arches, depends on the planned lengthening.
- Rail size depends on the planned lengthening.
- Techniques to increase frame stability include:
  - Increase number of half-pins
  - Increase diameter of the half-pins (pin diameter should not exceed a third of the bone diameter)
  - Greatest possible angle between half-pins (maximum, 90-degree angle)
  - Reduce distance between the bone and the external frame.
  - Increase the distance between half-pins.
  - Fixation as close to the corticotomy as possible.

**Femoral Lengthening**
- For simple lengthening (without deformity), three-point fixation is required in each segment.
- Use guidewire technique to place the first half-pin in the distal femur. A guidewire is introduced parallel to the knee joint line and proximal to the growth plate in children.
- Because the femur has a natural anterior bow, the guidewire is placed slightly anterior (not central) in the lateral femoral cortex (TECH FIG 7A, #1).
- The bone is drilled over the guidewire with a 4.8-mm or 3.2-mm cannulated drill bit (depending on the size of half-pin to be used). Then a self-tapping, hydroxyapatite-coated half-pin is introduced in the drilled track (TECH FIG 7B, #1).
- Attach this half-pin to the clamp, which is connected to the rail (monolateral fixator).
- At least one fingerbreadth of distance is maintained between the external frame and the lateral surface of the proximal thigh.
- A second half-pin is introduced in the proximal femur perpendicular to the biomechanical axis and fixed to the proximal clamp (TECH FIG 7B, #2).
- This half-pin is also placed slightly anterior (not central) in the lateral femoral cortex (TECH FIG 7A, #2).
- With intraoperative fluoroscopy, check the AP and lateral relationships of the frame with the femur. The frame should be located parallel to the biomechanical axis on the AP view (TECH FIG 7B, #3). On the lateral view, all the holes of the proximal and distal clamp should overlie the bone.
- Introduce two or more half-pins through the empty holes of the proximal clamp (TECH FIG 7B, #4).
During femoral lengthening, soft tissue tension predisposes the femur to develop procurvatum deformity. Procurvatum deformity can be prevented by making simple adjustments during frame application. After the proximal half-pins have been placed, the rail is disengaged from the proximal clamp. The distal clamp is then angulated by 10 degrees anteriorly (TECH FIG 7C).

The additional two half-pins are then placed in the distal clamp. This pin placement creates a mild recurvatum deformity (10 degrees), which compensates for the predicted procurvatum deformity.

At this point the frame is removed in preparation for corticotomy. The distance between the clamp and the skin is marked on the half-pins.

Gloves are changed, and the skin at the level of the corticotomy is prepped again.

The femoral corticotomy is completed following the same principles discussed earlier.

After completion of the corticotomy, the frame is reapplied, maintaining the same distance between the clamps and the skin.

Fluoroscopy is used to confirm the slight recurvatum deformity. This recurvatum deformity compensates for the procurvatum tendency during lengthening of femur.

The skin is closed after repair of the tensor fascia.

The distraction device is connected to the clamps, and final tightening is performed.

Half-pins are dressed with Xeroform gauze and sponges.

**Tibial Lengthening**

For simple lengthenings (without deformity), two- or three-point fixation is required in each bony segment.

The tibial frame usually includes a proximal clamp or arch with two or three half-pins and a distal fixation clamp with two or three half-pins.

Fibular osteotomy is performed first (as discussed previously).

A distal tibia-fibula transfixation screw is required to prevent distal tibia-fibula subluxation.

The skin is incised over the tibial corticotomy site, which usually is the proximal metaphysis.

Prophylactic fasciotomy of the anterior compartment is performed under direct vision before frame application.

Now a temporary suture is placed at the corticotomy skin incision, and corticotomy is performed after pin fixation is complete.

Two half-pins are introduced in the proximal tibial metaphysis perpendicular to the shaft and distal to the growth plate (TECH FIG 8, #1). The half-pins are placed
in the anteromedial and anterolateral cortex, with care to avoid the tibial tuberosity.

- The half-pin configuration should aim for pin spread of 90 degrees. The half-pins are introduced at different levels. The first half-pin is placed freehand. The arch is placed parallel to the proximal tibial joint line, and the second half-pin is placed through the clamp.

- The anterior aspect of the arch should be at least a fingerbreadth from the anterior cortex.

- In the absence of deformity, the mechanical and anatomic axis of the tibia are the same. The mounted frame should be parallel to the biomechanical axis in both the AP and lateral views (TECH FIG 8, #2).

- A half-pin is then introduced in the distal tibia through the clamp (TECH FIG 8, #3). Once again, parallel alignment of the frame with the mechanical axis is confirmed.

- Two additional half-pins are placed distally through the distal clamp (TECH FIG 8, #4).

- The distance of the clamps from the skin is marked on the half-pins. The frame is then removed in preparation for the corticotomy.

- Gloves are changed, and the skin at the level of the proximal tibial metaphysis is prepared again.

- The tibial corticotomy is completed following the same principle discussed earlier (TECH FIG 8, #5).

- The frame is reapplied, maintaining the same distance between the clamps and the skin as measured before the corticotomy.

- A properly executed procedure will not have any residual displacement at the corticotomy site.

- The skin is closed, leaving the underlying fascia open.

- The distraction device is connected to the clamps, and final tightening is performed.

- Half-pins are dressed with Xeroform and sponges. A pressure dressing is applied over the corticotomy site.

- The foot is placed in a plantigrade position.

**PEARLS AND PITFALLS**

**Intraoperative**

- Incomplete osteotomy will not allow distraction. Identify this intraoperatively and complete the corticotomy. Confirm complete osteotomy with fluoroscopy by externally rotating the distal fragment.

- Avoid neurovascular injury by placing half-pins and wires through the safe zones. Use cross-sectional atlas in operating room.

- Skeletal muscle relaxants may mask intraoperative nerve injury, and paralyzing agents are avoided.

**Distraction period**

- Prevent joint contracture by reducing or stopping distraction temporarily, increasing physical therapy, and using static or dynamic splinting of the joint.

- To prevent subluxation and dislocation of an adjacent joint during limb lengthening:
  - Correct hip instability before performing femur lengthening.
  - Extend the frame across the knee joint in the setting of cruciate ligament laxity.
  - Maintain full knee extension using nighttime static splinting.
POSTOPERATIVE CARE

- Distraction is started after a latency period of 7 to 10 days (depending on the age of the patient, the level of the corticotomy, and the local blood supply).6,11,18
- The rate of distraction is 1 mm per day, distributed as 0.25 mm four times a day.6,11,18
- Pin care is done with half-strength hydrogen peroxide and normal saline.
- Showering is allowed 1 week after the surgery, with antibacterial soap.
- Full weight bearing is encouraged as tolerated.
- Physical therapy to maintain range of motion and prevent contractures:
  - Minimum: three times a week, and a home program is performed four times a day
  - During active lengthening, the patient is seen once per week.
- Routine perioperative intravenous antibiotic prophylaxis is used.

OUTCOMES

Ilizarov Technique

- In 1995, Stanitski et al23 reported the results of 36 femoral lengthenings in 30 consecutive patients using the Ilizarov technique. The etiology of femoral shortening was congenital in 21 femurs and acquired in 15. The average lengthening was 8.3 cm (range, 3.5 to 12 cm), with a treatment time of 6.4 months (range, 2.5 to 12 months). Complications included premature consolidation in four patients, malunion of more than 10 degrees in two patients, and residual limb length inequality (less than 2 cm) in two patients. Two patients developed knee subluxation. There were no reports of osteomyelitis, ring sequestra, neurologic or vascular compromise, compartment syndrome, hypertension, or hip or knee dislocations in their series. Psychological problems necessitated cessation of lengthening in two patients.
  - These results show a significant improvement over previous reports of earlier techniques of femoral lengthening in terms of greater lengthening, simultaneous deformity correction, and fewer major complications.
- Stanitski et al24 reported tibial lengthening for 62 tibiae in 52 patients using the Ilizarov technique. The average lengthening was 7.5 cm (range, 3.5 to 12 cm). Twenty-eight (22%) patients required unplanned procedures, which included osteotomy for malunion or deformation of the regenerate and Achilles tendon for persistent equinus contracture. The complication rate decreased after the initial learning curve.

Monoplanar Fixator

- Coleman and Noonan4 reported results of distraction osteogenesis in 114 femurs and 147 tibias treated with monoplanar external fixator for a variety of different conditions. Mean femoral lengthening was 11 cm, or 48% of the original femur length. The femora that gained more length (expressed as percentage of original length) had poor healing indices.
  - Interestingly, LLD was more difficult to correct with distraction osteogenesis than short stature. In tibia the mean tibial lengthening was 9 cm or 41% of the original tibial length. The mean healing index was 32 days per centimeter of lengthening. The complication rate was 1.33 per tibia. Seemingly, obstacles or problems were also considered as complications in their study.
  - Overall, good results were obtained. They concluded that larger lengthenings are possible, but the cost is increased time and complications.

COMPLICATIONS

Intraoperative

- Ilizarov method: Compartment syndrome is rare, but may occur early following the surgery. Pain with passive stretch and paresthesia are important clinical signs of compartment syndrome. Measure compartment pressures and decompress the affected compartment as needed. Prophylactic anterior compartment release may be performed at the time of corticotomy.18,19
- Monoplanar fixator
  - Incomplete corticotomy: Confirm complete corticotomy by externally rotating the distal fragment under fluoroscopic imaging.
  - Avoid neurovascular injury by placing half-pins through safe zones.5 Use a cross-sectional atlas.
  - Avoid paralyzing anesthetic agents during surgery, because they may mask nerve injury.5,19

Distraction Period

- Pin tract infection initially is treated with a short course of oral antibiotics (7 to 10 days) and appropriate pin tract care. If infection persists, consider intravenous antibiotics or removal of the wire or half-pin with curettage of the infected site.
- Premature consolidation may be due to incomplete osteotomy, slow distraction rate, or incorrect direction of distraction.
- Neurologic symptoms may arise in the form of altered sensation or weakness of the muscle. The wire or half-pin is removed if direct contact or irritation of the nerve is suspected. Stretching of the nerve with rapid distraction may result in nerve injury, and it may be necessary to decrease the rate of distraction or even stop distraction temporarily.5,19,25
- Surgical nerve decompression occasionally is required to release the nerve from compressing structures.
- Unplanned deformity may develop during bone lengthening. Appropriate frame modifications may be required to correct the deformity.12,19
- Joint contractures may occur during lengthening. Treatment includes increasing the number of physical therapy sessions and use of dynamic splinting, especially to prevent equinus contracture.
- Iatrogenic deformity may develop during lengthening. Frame modifications may be required to correct the deformity and maintain a neutral mechanical axis.7-8
  - Compartment syndrome is rare (the anterior compartment is always released intraoperatively) but may occur following surgery. Paresthesia, pain with passive stretch, and pain out of proportion to the surgical procedure are clinical indicators of compartment syndrome. Compartment pressures should be measured, and compartments should be released as needed.4

Consolidation Period

- Pin tract infection (as described earlier).
- Delayed consolidation of regenerate may respond to electrical or ultrasound bone stimulator. The frame can be dynamized or the regenerate can be compressed by 0.5 cm.
After Frame Removal

- The regenerate bone may deform after premature frame removal (eg, poor regenerate, fewer than three continuous cortices). This can be prevented by frame dynamization prior to frame removal and protected weight bearing.
- Assess the regenerate bone clinically and radiographically at the time of frame removal. Consider use of a cast or brace and protected weight bearing in the setting of questionable bone regenerate.
- Stress fracture can occur either at the site of half-pins, especially when the half-pin size exceeds one third the diameter of the cortex, or through the regenerate bone. Fracture is treated with reapplication of the frame, casting, intramedullary rod fixation, or plate application.5

REFERENCES

DEFINITION
- Physiologic genu varum (before age 2) and genu valgum (before age 6) are ubiquitous in children. These deformities are self-correcting and need no intervention.
- At maturity, limb lengths should be symmetric, or at least within 2 cm of each other.
- However, various pathologic processes may cause progressive and harmful angular deformities of the knee or knees, with or without limb-length discrepancy.
- With the insidious deviation of the mechanical axis, secondary ligamentous laxity, patellofemoral instability, and joint subluxation may ensue, resulting in gait disturbance and functional limitations.
- These findings may be unilateral or bilateral, involving the femur, tibia, or both. The deformities may or may not be symmetric.
- Concomitant torsional deformities and length discrepancy of greater than 2 cm may complicate matters.

ANATOMY
- During standing, the normal knee joint line and physes remain horizontal. The mechanical axis, represented by a line joining the center of the hip and center of the ankle, should bisect the knee at an angle of 87 degrees with respect to the joint line (FIG 1A). Allowing for normal variation, the mechanical axis should at least fall within the inner two quadrants (+1 or −1) of the knee (FIG 1B).
- The distal femur normally has about 6 degrees of anatomic valgus relative to its shaft, expressed as a lateral distal femoral angle (LDFA) of 84 degrees.
- The proximal tibia has 3 degrees of varus relative to its shaft; consequently, the medial proximal tibial angle (MPTA) is 87 degrees.
- Weight-bearing forces are relatively evenly divided between the medial and lateral compartments. This results in physiologic loading of the articular surfaces and physes.
- The patella remains centered in the femoral sulcus, guided by the retinacula.

PATHOGENESIS
- Intrinsic weakness within the femoral or tibial epiphyses or physes may inhibit growth, resulting in deviation of the mechanical axis.
- Progressive deviation invokes the Hueter-Volkmann principle, where excessive and chronic compression further inhibits articular and physeal cartilage growth. Thus, a vicious cycle is established, perpetuating the problem (FIG 2A).
- An arthrogram may help to demonstrate the phenomenon of delayed ossification due to malalignment (FIG 2B).
- Direct or indirect trauma may result in physeal damage, with either restricted growth or occasionally overstimulation of growth.
- Secondary effects on the extensor mechanism and patellofemoral joint may compound issues related to genu valgum, and patellar instability may ensue.
- Length discrepancy that is predicted to exceed 2 cm at maturity may warrant surgical intervention; epiphysiodesis is a good option for the 2- to 5-cm range.

NATURAL HISTORY
- The natural history of physiologic knee deformities is spontaneous resolution, without the need for braces, therapy, or surgery.\(^3\)
- The natural history of pathologic deformities is progressive valgus or varus resulting in knee instability and joint deterioration. As the ground reaction forces are displaced medially or laterally, eccentric compression of the distal femur and proximal tibia exceeds their loading tolerance and inhibits normal growth, not only of the physis but of the epiphysis as well (Hueter-Volkmann effect).
- Gait disturbance and functional limitations will ensue, often accompanied by pain.\(^6\)

FIG 1 • A. The mechanical axis is a line drawn on a full-length standing AP radiograph of the legs, preferably with the pelvis leveled and the patellae facing forward. Connecting the center of the head and ankle, it should bisect a horizontal knee. B. Dividing the knee into quadrants, the axis should pass within medial or lateral zone one, allowing for physiologic variations. Mechanical axis deviation into zone 2 or 3 is an indication for surgical intervention.
PATIENT HISTORY AND PHYSICAL FINDINGS

- Family history may yield important clues regarding the cause and natural history of deformities. The parents and siblings have often been subjected to corrective osteotomies.
- The patient presents with knock knees or bowlegs; the deformity may be unilateral or bilateral. There may be concomitant limb-length discrepancy with both true and apparent foreshortening of the involved limb.
- Knock knees may be accompanied by outward femoral or tibial torsion (or both). Medial collateral laxity may permit medial knee thrust.
- Patellar instability is not uncommon as the deformity progresses. Circumduction gait is inevitable and problematic for walking and running.
- Knock knees are documented by measuring the intermalleolar distance while the patient is standing with the knees touching (patellae neutral) (**FIG 3A**).
- Bowlegs may be accompanied by inward tibial torsion and intoeing. Lateral ligament laxity may permit lateral knee thrust during walking.
- Bowlegs are readily documented by measuring the intercondylar distance while the patient is standing with the feet together (patellae neutral) (**FIG 3B**). This should corroborate the mechanical axis deviation from the center of the knee that is measured on the standing radiograph (**FIG 3C**).
- The spine and feet should be evaluated as well.
- Orthotics may provide knee support but will have no corrective effect upon growth. Whether this is due to suboptimal design or compliance issues is a matter of debate.
- Physical examination should include observation of stance, knee alignment, torsional profile, limb lengths, and gait.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Weight-bearing anteroposterior (AP) and lateral views of the lower extremities are obtained with the patellae facing forward. For limb-length discrepancy, the pelvis is leveled with blocks.
- A patellar view may document patellar tilt or subluxation.
- Estimation of skeletal maturity (hand or elbow film) may be useful. Guided growth requires at least 6 months to produce demonstrable improvement in alignment.
- Computed tomography (CT) scan or magnetic resonance imaging (MRI) is obtained if a physeal bar is suspected. A “gunsight” CT is obtained for “miserable malalignment” (femoral plus tibial torsion) (**FIG 4**).
- The landmarks for femoral measurement are a line that bisects the femoral neck versus a line crossing the back of the femoral condyles (normal, 11 to 15 degrees).
For the tibia, it is a line across the back of the condyles versus the bimalleolar axis (normal, 15 to 20 degrees).

**DIFFERENTIAL DIAGNOSIS**
- Genu valgum
  - Idiopathic genu valgum (see Fig 3A)
  - Hereditary multiple exostoses
  - Cozen fracture (proximal tibial metaphysis)
  - Congenital limb anomalies
  - Postaxial hypoplasia
  - Neuromuscular disorders: cerebral palsy, spina bifida
  - Down syndrome
- Genu varum
- Blount disease
- Rickets
- Osteochondral dysplasia (see Fig 3B,C)
- Ollier disease
- While the underlying diagnosis (see above) has often been established, the cause has little relevance to the treatment. The degree of deformity and the evolution of symptoms dictate the timing and need for intervention.

**NONOPERATIVE MANAGEMENT**
- Activity restriction and nonsteroidal anti-inflammatories are not definitive treatments. Valuable time may be wasted, and there is no logical endpoint to this form of management.
- Physical therapy remedial exercises are of no lasting benefit with respect to the established growth pattern.

- While knee bracing may compensate for muscle weakness or secondary ligamentous laxity, it may not predictably effect growth modulation or improvement in skeletal alignment.
- Furthermore, adequate braces are cumbersome and expensive, so noncompliance may be an issue.

**SURGICAL MANAGEMENT**
- Any child or skeletally immature adolescent being considered for corrective osteotomy may be a candidate for guided growth.
- As long as the physis are open, hemiepiphysiodesis or guided growth offers advantages and has few associated complications compared to more invasive osteotomies.
- The indications for surgery include progressive deformity resulting in gait disturbance, functional limitations, and pain. Many patients have already exhausted other options, including nonsteroidal anti-inflammatories, bracing, activity restriction, and physical therapy or even osteotomy.
- Options for growth modulation include:
  - Phemister bone block: permanent; requires precise timing and close follow-up
  - Percutaneous drilling: permanent; same drawbacks as Phemister technique
  - Epiphyseal stapling (Blount): rigid implant compresses dynamic physis
  - Percutaneous screw (Metaizeau): reversibility unknown; rigid implant violates or compresses the physis; limited applications (adolescence, frontal plane deformities)
  - Guided growth with eight-plate (Stevens): reversible; tension band principle; versatile (any age, diagnosis, or plane)

**Preoperative Planning**
- Both the clinical examination and appropriate radiographs should reveal and document varus or valgus deformities of the knee as well as limb lengths. The torsional profile should be documented.
- When indicated, bilateral or multilevel surgery may be accomplished at one sitting (outpatient).
- Length discrepancies and rotational malalignment may not be directly addressed by guided growth. However, relative
length is gained and there may be subsequent rotational improvement when the mechanical axis is restored to neutral.
- Occasionally an intraoperative arthrogram will demonstrate the true shape of the articular surfaces (see Fig 2B).
- A modular approach may permit angular correction to neutral mechanical axis, followed by length adjustment.

**Positioning**
- The patient is positioned supine on the operating table.
- Fluoroscopy is recommended.

**GUARDED GROWTH: EIGHT-PLATE**
- With the patient in the supine position and (preferably) under tourniquet control, the medial or lateral aspect (or both) of the distal femoral or proximal tibia (or both) are identified fluoroscopically and 2- to 3-cm skin incisions are marked.⁶,⁷
  - It is helpful to inject them with 0.25% Marcaine for postoperative comfort.
- When approaching the medial femur, the fascia of the vastus medialis is incised parallel to its inferior border, and the muscle is retracted. On the lateral femoral approach, the iliobial band is split longitudinally. Over the medial tibia, the medial collateral ligament is split longitudinally; over the lateral tibia, the anterior compartment muscles are left intact and the fibula is undisturbed.
- The dissection is deepened sharply, dividing fascia and retracting muscles as necessary but preserving the periosteum.
- A Keith needle is inserted into the physis (this characteristically feels like pushing a needle into a bar of soap), and the position and direction are confirmed with the image intensifier.
- The 12- or 16-mm plate (surgeon preference) is centered on the Keith needle using the middle hole; it is inserted deep to the soft tissues to rest in an extraperiosteal position.
- The 1.6-mm smooth guide pins are inserted, placing the epiphyseal one first, followed by the metaphyseal pin.
- The cortex is drilled to a depth of 5 mm to permit insertion of the 24- or 36-mm (surgeon preference) fully threaded, cannulated, self-tapping screws (TECH FIG 1).
  - The screws do not have to be parallel or to match in length.
- If the position looks good, the guide pins are removed and the screws are further tightened so that the heads are countersunk in the plate.
- After routine wound closure, a soft compression dressing is applied.

**STAPLING (BLOUNT)**
- The surgical approach is the same, preserving the periosteum.
- A guide needle is inserted.
- Thigh tourniquets are employed for speed and accuracy of hardware placement.

**Approach**
- The surgical approach is minimally invasive, directly over the physis, at the apex of the deformity.
- Hardware should be midsagittal unless correcting an oblique or sagittal-plane deformity. Placement is confirmed with fluoroscopy and the implant position is adjusted as needed.

**Tech FIG 1**
- **A.** The eight-plate instrumentation includes a soft tissue guide with 1.6-mm cannulation for the guide pin and 3.2 mm for the “stubby” drill that permits a 5-mm depth of penetration. **B.** The 4.5-mm screws are cannulated and self-tapping and come in three lengths: 16 mm (shown here), 24 mm, and 32 mm. **C,D.** The plate application is extraphyseal, over a localizing guide pin, while preserving the periosteum. Any open and approachable physis may be instrumented for correction in the frontal, sagittal, or oblique planes as well as for length correction.
- One to three rigid Blount staples (Zimmaloy) are inserted per physis.
- Simple closure is done with a elastic bandage.
Part 4 • PEDIATRICS • Section III  RECONSTRUCTION

TECHNIQUES

PERCUTANEOUS SCREW (METAIZEAU)

- Under fluoroscopic guidance, a single 7.3-mm transphyseal screw is placed either from the medial or lateral side of the bone, crossing the physis near its perimeter.
- The goal is to place the tip of the screw just inside the medial or lateral aspect of a given physis to effect angular growth.
- Upon correction to neutral, the screw is removed.

PHEMISTER

- This approach is mainly of historic interest.
- The same approach is used as for stapling or eight-plate.
- Periosteal flaps are raised to visualize the physis.
- A bone rectangle is removed and inverted to establish a bony bridge.
- This technique is permanent and thus most suitable for teenagers. It requires precise timing and calculations.

PERCUTANEOUS EPIPHYSIODESIS (MODIFIED FROM PHEMISTER)

- Under fluoroscopic guidance the physis is drilled or curetted (or both) to produce a bony physeal bar.
- The requisite depth of penetration has yet to be specified.
- There may be a delay in effect until a bone bridge is established.
- This technique is permanent and thus suitable only for teenagers. It requires precise timing and calculations.

PEARLS AND PITFALLS

Follow-up
- Parents should be educated about the importance of routine periodic follow-up; typically follow-up is done every 3 months (FIG 5A, B).

Staples
- If stapling is part of the procedure, forewarn parents about possible hardware migration or breakage requiring revision surgery (FIG 5C).

Periosteal damage
- Periosteal damage should be avoided during hardware insertion or removal.

FIG 5 • A. This 12-year-old boy, stapled for unilateral genu valgum, failed to return for follow-up for 14 months and overcorrected into varus. The staples were removed and eight-plates inserted laterally. Had he had physeal drilling, the only salvage would have required femoral and tibial osteotomies with lengthening or contralateral epiphysiodesis. B. A 14-year-old boy 1 year after tibial stapling for limb-length inequality due to congenital clubfoot. The lateral staples have loosened, resulting in mechanical axis deviation into medial zone 2. A lateral eight-plate corrected this iatrogenic varus deformity to neutral. C. This 12-year-old girl with neurofibromatosis was stapled for length discrepancy. One year later her staples inexplicably had migrated (medial more than lateral), causing iatrogenic varus and requiring unplanned reoperation. Through bending, these narrow-gauge staples have afforded dramatic correction of fixed knee flexion deformity. It is impossible to tell, however, if or when they might break, and periosteal damage will be unavoidable upon removal.
POSTOPERATIVE CARE
- No immobilization is required.
- Immediate weight bearing is permitted.
- No activity restriction is imposed.
- Follow-up is done at 3-month intervals with weight-bearing AP radiographs of the legs when clinically straight.
- Hardware is removed, avoiding periosteal damage, when the mechanical axis is neutral or limb lengths are equal.
- Continued follow-up is important. Guided growth can be repeated if rebound growth causes recurrence.
- Osteotomy may be reserved for rotational correction or further length equalization.

OUTCOMES
- Initially after hemiepiphysiodesis there is no visible difference, and the family needs to be forewarned of this.
- The correction is gradual and subtle, and therefore routine follow-up is imperative.
- Correction to neutral (eight-plates) will take 12 months on average; staples take somewhat longer.
- The hardware is removed upon correction of the valgus or varus deformity. (The surgeon must preserve the periosteum!)
- Follow-up should continue until maturity to watch for recurrent deformity due to rebound growth. While this is unpredictable, it will be evident within 12 months of hardware removal.
- Premature physeal closure is unlikely, provided the hardware is inserted and removed uneventfully, leaving the periosteum intact.
- Because the plate–screw construct is flexible and serves as a tension band, it is unlikely to break or migrate, making revision surgery less likely.
- Modular adjustment of limb lengths is convenient and simple to accomplish.
- If secured with cannulated screws, eight-plate survivorship is rarely problematic.

COMPLICATIONS
- There is a race between deformity correction and hardware failure. Failure is more likely with a rigid implant.
- The rigid staples are at a disadvantage owing to occasional migration or breakage, necessitating unplanned revision surgery (FIG 6).
- A bent staple may permit excellent correction but is more difficult to monitor and remove.

REFERENCES
DEFINITION
- Angular deformities of the distal tibia can lead to varus or valgus malalignment of the ankle joint.
- Additional sources of ankle malalignment include both bony and ligamentous disorders.

ANATOMY
- Normally, the tibiotalar joint is in neutral alignment. This is assessed by measuring the lateral distal tibial angle (LDTA), which has a normal value of 90 degrees (range, 88 to 95 degrees).
- Sagittal alignment of the ankle joint is normally in slight dorsiflexion and is assessed by measuring the anterior distal tibial angle (ADTA), which has a normal value of 80 degrees (range, 78 to 81 degrees).

PATHOGENESIS
- Coronal plane deformities about the ankle are not uncommon and may occur secondary to congenital or acquired conditions.1–3
- Varus angular malalignment of the ankle is generally due to either a traumatic or infectious insult to the medial aspect of the distal tibial physis, with resultant premature closure of the injured area and relative overgrowth of the lateral distal tibial physis and fibula.2,3,7
- Valgus deformity of the ankle in children is associated with a wide variety of conditions. Relative overgrowth of the medial aspect of the distal tibial physis can occur as a result of fibular shortening or hypoplasia. Longitudinal deficiency of the fibula may be due to premature distal fibular physeal closure, fibular nonunion, malunion, congenital pseudarthrosis of the fibula, or longitudinal deficiency of the fibula, or it may occur after harvest of a portion of the fibula for bone grafting. In addition, progressive ankle valgus with lateral wedging of the distal tibial epiphysis may be seen in patients with myelodysplasia.2,3,7
- Deformities occurring secondary to physeal injuries are progressive.
- Correction of deformities about the ankle is complicated by the fact that deformities are frequently centered about the distal tibial physis, very close to the ankle joint.
- Because the deformity is often centered very close to the joint, opening or closing wedge osteotomies performed proximal enough to allow fixation of the fragments often produce unacceptable translation of the ankle joint.

NATURAL HISTORY
- Angular deformity of the distal tibia leads to abnormal loading of the hindfoot, ankle joint, and knee, and may lead to secondary deformities such as a planovalgus foot or hallux valgus. Long-term malalignment of the ankle joint may lead to the development of premature osteoarthritis of the ankle.8,9
- Initially, the limb may be treated with braces or orthotics without difficulty. However, progression of the deformity with growth leads to increased soft tissue pressure, bursa formation, and risk of skin ulceration over the medial malleolus, lateral malleolus, or talonavicular region.

PATIENT HISTORY AND PHYSICAL FINDINGS
- A detailed history should be obtained, including recent or remote trauma, infection, or congenital conditions. In addition, symptoms related to ankle malalignment or instability should be elicited.
- Physical examination should include gross inspection of both lower extremities with the patient standing, walking, and sitting to determine the location of deformity as well as the alignment of adjacent structures (in particular the hindfoot and knee) that may contribute to perceived deformity as well as affect the surgical outcome.
- The clinician should inspect standing foot and ankle alignment from behind the patient to determine the location of deformity (distal tibia, ankle, hindfoot).
- Standing heel alignment in varus or valgus may indicate the presence of uncompensated distal tibial deformity. Normal alignment in the presence of deformity alerts the surgeon to hindfoot compensation, which may be rigid or supple.
- The clinicians should check hindfoot passive inversion and eversion to evaluate the ability of the hindfoot to accommodate surgical changes.
- Lack of hindfoot motion can alert the surgeon that the patient may not be able to compensate for distal tibial osteotomies. Further procedures may be warranted to realign the hindfoot to correct fixed deformities.
- Single-limb toe rise: With the patient standing, viewed from posterior, the patient lifts one limb, then rises onto the toes of the standing limb. This should result in prompt inversion of the heel, rising of the longitudinal arch, and external rotation of the supporting leg. Lack of hindfoot inversion should draw attention to the subtalar and transverse tarsal joints as possible sites of pathologic alignment.
- To check forefoot–hindfoot alignment, the patient is seated, facing the examiner. The patient’s hindfoot is grasped in one hand and the calcaneus is held in the neutral position, in line with the long axis of the leg. The examiner’s other hand grasps the foot along the fifth metatarsal. The thumb of the hand grasping the heel is placed over the talonavicular joint, and the joint is manipulated by moving the hand holding the fifth metatarsal until the head of the talus is covered by the navicular. The position of the forefoot as projected by a plane parallel to the metatarsals is compared to the orientation of the long axis of the calcaneus. The forefoot will be in one of three positions relative to the hindfoot—neutral, forefoot varus, or...
forefoot valgus. The examiner should determine whether this relation is supple or rigid, especially when considering surgery, since a fixed varus or valgus forefoot deformity will not allow the foot to become plantigrade after realignment of the tibiotalar or subtalar joints.

- Standing lower extremity alignment: If distal tibial deformity is present in conjunction with genu varum or valgum, the patient’s entire deformity should be evaluated and a comprehensive plan developed.
- The patient’s gait may show an antalgic pattern or may reveal limitations of functional motion in the hindfoot.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Standing anteroposterior (AP) and mortise views of both ankle joints should be obtained (FIG 1A–C). The LDTA is measured from the intersection of a line drawn parallel to the long axis of the tibia and a second line drawn across the dome of the talus. The normal LDTA is 90 degrees as measured from the lateral side. The amount of deformity is calculated from the number of degrees that differ from 90 degrees.
- Lateral weight-bearing radiographs of both ankles should be obtained to detect any sagittal plane deformity (FIG 1D). The lateral tibiotalar angle is measured from the anterior side. The average ADTA is 80 degrees as measured from the anterior side.
- Foot radiographs, including standing AP, standing lateral, and oblique views, are used to evaluate hindfoot alignment to avoid over- or undercorrection at the time of surgery. The standing lateral view of the foot is used to evaluate talar–first metatarsal alignment; normally, the talus and first metatarsal are parallel. The standing AP view is used to evaluate the talocalcaneal angle; if the talocalcaneal angle exceeds 35 degrees, hindfoot valgus is present.
- A standing AP view of the pelvis is obtained to evaluate for leg-length discrepancy.
- Computed tomography can be useful in assessing the presence and size of physeal bars.

**DIFFERENTIAL DIAGNOSIS**

- In addition to distal tibial angular deformity, varus or valgus malalignment about the ankle joint may be due to other local bony or ligamentous disorders.
- Fixed hindfoot varus or valgus may simulate ankle deformity on clinical examination.
- Apparent ankle valgus may occur secondary to disorders such as angular deformity of the fibula with shortening and associated lateral shift of the talus hindfoot valgus, hindfoot valgus, or fixed forefoot varus.
- Apparent ankle varus may occur secondary to disorders such as hindfoot varus as seen in Charcot-Marie-Tooth disease, residual clubfoot, or fixed forefoot valgus.

**NONOPERATIVE MANAGEMENT**

- Mild distal tibial angular deformity associated with ankle varus or valgus can be managed through the use of custom braces and orthotics or medial or lateral posting of the shoes.
- Surgery is the mainstay of treatment of bony deformity of the distal tibia.

**SURGICAL MANAGEMENT**

- An opening or closing wedge supramalleolar osteotomy (SMO) may be performed for simultaneous correction of frontal- and sagittal-plane deformities of the ankle.
- SMOs allow for immediate correction of the deformity. However, they are considered technically demanding and relatively invasive and require a period of limited weight bearing or non-weight bearing and immobilization.
- The challenge involved in correcting varus or valgus deformities of the ankle is to correct the deformity without introducing new secondary deformities. The mechanical axis of the tibia should pass through the center of the ankle perpendicular to the joint surface.
- Some SMO techniques may lead to the development of secondary deformities. For instance, a transverse closing wedge osteotomy performed 4 cm proximal to the joint surface to correct a valgus deformity causes lateral shift of the ankle and a prominent medial malleolus.

---

**FIG 1**

A. Standing AP view of both ankles in a 14-year-old boy with a left distal tibial valgus deformity due to congenital pseudarthrosis of the tibia. B. Standing AP radiograph of the left ankle in a 16-year-old boy showing a varus deformity after a healed physeal distal tibial fracture with medial physeal arrest. C. Standing lateral radiograph of the left ankle of the same patient. D. Standing mortise radiograph of the left ankle in the same patient showing a varus deformity after a healed physeal distal tibial fracture with medial physeal arrest.
In a child with growth remaining, physeal modulation via a hemiepiphysiodesis with an eight-hole plate, transphyseal screw, or staples can be used to correct distal tibial valgus deformities.

Correction occurs gradually after hemiepiphysiodesis, so it is not ideal for patients requiring acute corrections such as those with skin breakdown or significant pain. Close follow-up after hemiepiphysiodesis is essential to avoid over-correction.

Currently, SMOs are the procedure of choice for correcting ankle valgus in the absence of adequate growth to correct the deformity by hemiepiphysiodesis techniques.

Deciding on the Technique

Several techniques have been used and are described below, including transphyseal SMO, transverse SMO with translation, and the Wiltse SMO.

- Oblique supramalleolar opening or closing wedge osteotomy
  - Lubicky and Altiok\(^3\) described an oblique distal tibial osteotomy to correct varus and valgus deformity of the distal tibia.
  - This technique offers the advantage of placing the hinge of the osteotomy at the level of the deformity and thus performing the correction at the site of the deformity so that maximum correction can be obtained without creating a secondary translational deformity.

- Transverse supramalleolar osteotomy with translation: Concomitant fibular osteotomies are performed to allow for compression at the osteotomy site and translation of the tibial osteotomy.

- Wiltse osteotomy
  - Wiltse\(^6\) noted that a simple wedge resection for correction of distal tibial valgus deformities will lead to malalignment and prominence of the medial malleolus.
  - The author developed and reported the results of resection of a triangular section from the distal tibia with rotation of the distal fragment in order to produce a normal-appearing ankle and improved weight-bearing alignment.

- This procedure is effective because it creates a stable osteotomy and forces the surgeon to lateralize the osteotomy when correcting a valgus deformity, thereby bringing the ankle joint beneath the tibial shaft and preventing medial prominence of the medial malleolus.

- Screw hemiepiphysiodesis is used to address valgus deformities in children with sufficient growth remaining to correct the deformity.

- We have found that the oblique osteotomy allows for correction of the deformity and offers the advantage of improved bone healing as minimal periosteal stripping is necessary and the deformity is corrected by hinging the osteotomy at a point along the bisector of the deformity.

Preoperative Planning

- The principal issues to be addressed in surgical correction of distal tibial deformities are the magnitude and direction of the deformity, any rotational component, and length. The surgeon should address all of these components with a comprehensive plan.

- Length discrepancies in particular are critical because when the limb-length discrepancy is greater than 2 cm, a lengthening or shortening procedure should be performed in conjunction with correction of the distal tibia. Either contralateral epiphysiodesis or shortening should be planned or lengthening of the index limb, which may make the entire procedure preferable to perform with circular external fixation.

- Weight-bearing radiographs of the ankle in the AP and lateral planes are essential to determine the extent of the deformity. In addition, it is important to thoroughly assess the hindfoot and forefoot.

- The magnitude and plane of the deformity to be addressed should be calculated preoperatively and noted in the preoperative plan (FIG 2A).

- After the deformity is assessed using the methods described by Paley and Tetsworth,\(^4,5\) the position of the center of rotation of angulation (CORA) is identified and a bisector is constructed. Most commonly this point is very near the physis and articular surface (FIG 2B).
Although the osteotomy can be performed at a level consistent with the biology of the bone and allowing for adequate fixation, the correction of the deformity should occur along the bisector.

- The goal of surgical correction should be to obtain an LDTA of about 90 degrees with a tibial mechanical axis that passes through the center of the ankle.
- Care should be taken to evaluate the hindfoot motion preoperatively.
- Patients with fixed varus or valgus hindfoot alignment may require additional procedures, such as a calcaneal osteotomy, or the surgeon may elect to compensate for a mild fixed deformity by leaving the ankle in mild varus or valgus alignment, thereby bringing the hindfoot into neutral alignment.

Positioning

- The patient is placed in the supine position on a radiolucent operating table with a bolster placed under the ipsilateral hip. A well-padded nonsterile tourniquet is placed around the ipsilateral proximal thigh.
- Intraoperative fluoroscopy is essential. The C-arm should be placed on the opposite side of the table. The C-arm monitor should be placed with the image intensifier on the opposite side of the table from the limb to be corrected.

Approach

- Distal tibial osteotomy is performed through either a medial incision centered over the medial malleolus or an anteromedial incision made slightly lateral to the anterior tibialis tendon.

MEDIAL APPROACH

- The proximal extent of dissection is determined by the size of the bone wedge to be resected in a closing wedge osteotomy or by the extent of the fixation required in an opening wedge.
- A medial incision is made directly along the medial border of the tibia extending from just proximal to the physeal to as far proximal as needed based on the size of the wedge to be removed for correction of the valgus deformities (TECH FIG 1).
- Care is taken to protect the saphenous vein and nerve. The distal tibia is exposed to a point just proximal to the physis. If the distal tibial physis is closed, the dissection can be extended beyond the physis and to the epiphysis if needed. The periosteum is divided sharply. This area is exposed subperiosteally anteriorly and posteriorly.
- After the tibia is exposed medially, a limited subperiosteal dissection is made anteriorly and posteriorly in an oblique direction down to the lateral aspect of the distal tibial physis. Crego or Chandler retractors are then placed to protect the soft tissues.

TECH FIG 1 • Placement of incision on the anteromedial aspect of the ankle for oblique osteotomy.

ANTERIOR APPROACH

- A longitudinal incision is made over the anterior aspect of the ankle extending distally to the ankle joint and proximally about 5 cm. The dissection should be carried down lateral to the anterior tibial tendon, protecting the anterior tibial artery and deep peroneal nerve laterally.
- Subperiosteal dissection is carried out around the tibia distally to the level of the physis. Crego or Chandler retractors are then placed medially and laterally to protect the soft tissues.
- If necessary, the fibular osteotomy is performed using a separate 2-cm lateral incision that parallels the fibula and is centered over the point of the osteotomy.

OBLIQUE SUPRAMELLLOAR OPENING OR CLOSING WEDGE OSTEOTOMY

- If the osteotomy is performed through a medial approach, the preplanned osteotomy is then performed with an oscillating saw to the physis, leaving the lateral cortex intact.

Valgus Deformities

- For valgus deformities, a second osteotomy is made at an angle to the first corresponding to the amount of deformity.
bone to be resected according to the preoperative plan. This is also done with a power saw, ending at the lateral extent of the first osteotomy, and the wedge is removed (TECH FIG 2A,B).

- The foot and ankle are then rotated into varus, closing the wedge while leaving the lateral hinge intact, and the correction is assessed using the image intensifier and if necessary plain radiographs. Additional bone can be removed from the proximal fragment if the amount of correction is insufficient.

- Once the osteotomy closes, the drill is passed through the medial malleolus in patients with a closed physis, securing the osteotomy. If the patient has an open physis, an oblique interfragmentary screw is passed across the osteotomy site beginning just proximal to the physis. The screw should be centered in the sagittal plane.

- If the fibula is an impediment to correction (it usually is not) an oblique osteotomy of the fibula is made and if necessary fixed with a plate and screws.

**Varus Deformities**

- For varus deformities, an opening wedge is created along the same line. Once the osteotomy is made, the osteotomy site is distracted using a lamina spreader to the preplanned distance to correct the deformity (TECH FIG 3A–C).

- It is then held open by a wedge-shaped tricortical iliac crest graft or simply stabilized with a medial plate and screws (TECH FIG 3D–H), beginning with a screw passed from medial to lateral across the osteotomy site.

- After wound closure, a short-leg non-weight-bearing cast is applied.

---

TECH FIG 2 • A. AP intraoperative view of the ankle showing a Crego elevator in place with a saw blade performing the initial osteotomy. **B.** AP intraoperative view of the ankle with a saw blade placed into the initial cut and the saw completing the second cut.

TECH FIG 3 • A. Position of the two Crego elevators used to protect the soft tissues during the oblique osteotomy. An oscillating saw is used to create the oblique osteotomy. Fluoroscopy is used to confirm the angulation of the cut as well as to ensure that the lateral cortex remains intact. **B.** A large osteotome is placed into the osteotomy site and used to open the osteotomy. **C.** A laminar spreader is used to hold open the osteotomy site. **D.** The amount of medial opening needed for deformity correction is verified by measuring the medial opening in millimeters. **E.** A bicortical 3.5-mm screw (cortical) is inserted from the proximal to distal fragments to hold the osteotomy site open, allowing for removal of the laminar spreader. **F.** A 3.5-mm small fragment dynamic compression plate is contoured to the medial aspect of the distal tibia. (continued)
Chapter 36  DISTAL TIBIAL OSTEOTOMY

**DISTAL TIBIAL OSTEOTOMY**

- The tibiotalar joint should be corrected to neutral at the time of surgery.
- A wedge of bone is resected, apex medial in valgus ankles and apex lateral in varus ankles. The angle of the wedge is based on preoperative radiographs. The wedge of bone is harvested so that continuity of the apex is maintained and acts as a hinge.
- An anteromedial longitudinal incision is made over the distal tibial metaphysis. The periosteum is incised medial to the tibialis anterior tendon. The surgeon should avoid cutting into the physeal perichondral ring distally. The periosteum is elevated and retracted with Crego retractors placed medially and laterally. The level of the distal tibial physis is checked using fluoroscopy.
- When addressing valgus deformities, a closing wedge osteotomy is performed in the metaphyseal bone about 3 cm proximal to the ankle joint. The proximal cut is made first. It is aligned perpendicular to the long axis of the tibia. The second distal osteotomy cut is made obliquely. The triangle formed by the two cuts is medially based. Enough bone is removed to convert the preoperative LDTA to neutral.
- Preoperatively, a sterile template triangle can be prepared with a piece of paper and a goniometer. The paper is placed on the tibia, which is marked with an osteotome and then cut with an oscillating saw.

**TRANSVERSE SUPRAMEALLEOLAR OSTEOTOMY WITH TRANSLATION**

- The tibiotalar joint should be corrected to neutral at the time of surgery.
- A wedge of bone is resected, apex medial in valgus ankles and apex lateral in varus ankles. The angle of the wedge is based on preoperative radiographs. The wedge of bone is harvested so that continuity of the apex is maintained and acts as a hinge.
- An anteromedial longitudinal incision is made over the distal tibial metaphysis. The periosteum is incised medial to the tibialis anterior tendon. The surgeon should avoid cutting into the physeal perichondral ring distally. The periosteum is elevated and retracted with Crego retractors placed medially and laterally. The level of the distal tibial physis is checked using fluoroscopy.
- When addressing valgus deformities, a closing wedge osteotomy is performed in the metaphyseal bone about 3 cm proximal to the ankle joint. The proximal cut is made first. It is aligned perpendicular to the long axis of the tibia. The second distal osteotomy cut is made obliquely. The triangle formed by the two cuts is medially based. Enough bone is removed to convert the preoperative LDTA to neutral.
- Preoperatively, a sterile template triangle can be prepared with a piece of paper and a goniometer. The paper is placed on the tibia, which is marked with an osteotome and then cut with an oscillating saw.

**WILTSE OSTEOTOMY**

- The osteotomy is performed through an anterior approach to the distal tibial metaphysis at the level of the metadiaphyseal junction.
- A triangular piece of bone is removed from the region of the distal tibial metadiaphyseal junction. The apex of the cut is centered on the longitudinal axis of the tibia.
- The magnitude of the angle of the lateral portion of the triangle should be equal in size to the magnitude of the deformity to be corrected.

**TECH FIG 3 • (continued)**

G. The plate is secured to the distal tibia with 3.5-mm cortical bone screws. H. Intraoperative AP radiograph showing opening wedge osteotomy with internal fixation.

- The fibular osteotomy, if necessary, is performed at the same level as the tibial osteotomy. The fibular osteotomy is performed because it allows for sufficient compression at the tibial osteotomy site, and it also allows for centralization of the distal tibial fragment to improve foot alignment.
- The tibial osteotomy may be fixed with a small fragment plate or Kirschner wires.
- The fibular osteotomy is made through a second incision, laterally over the fibula. The osteotomy is shaped in the form of a triangle. The proximal cut is oblique and ends proximal at the medial cortex. The distal cut is perpendicular to the shaft of the fibula.
- The extent of correction is checked with an intraoperative radiograph.
- Care is taken to avoid injury to the distal tibial physis when obtaining fixation of the osteotomy.
- Internal or external rotation deformities can be addressed at the same time.
- Alternatively, an opening wedge osteotomy may be performed about 2 to 3 cm proximal to the physis. An osteotomy is made parallel to the ankle joint, and an opening wedge correction is performed and filled with bone graft.
**POSTOPERATIVE CARE**

- After wound closure, a short-leg non-weight-bearing cast is applied. Non-weight bearing is maintained for 4 to 6 weeks.
- Closing wedge osteotomies are typically stable and patients are allowed full weight bearing at 4 weeks.
- Opening wedge osteotomies are stable based on fixation and grafting, and the patient is kept non-weight bearing for 6 weeks.
- After 4 to 5 weeks, when weight bearing is initiated, the cast is removed and a CAM walker is applied.
- Physical therapy should be instituted to regain motion, strength, and proprioception before resuming activities.
- It is important to follow immature patients closely for the development of a limb-length discrepancy, which can be addressed by performing an epiphysiodesis of the contralateral lower limb.
OUTCOMES
- Lubicky and Altiok\(^3\) reported their experience in 26 limbs with the oblique osteotomy and found rapid healing and few complications, with all patients resuming their preoperative level of activity.
- They noted that patients with preoperative hindfoot valgus had improved alignment with varus overcorrection of the distal tibia and recommended overcorrection by 5 degrees in these patients.
- We have not overcorrected patients with normal hindfoot alignment, particularly those with posttraumatic deformities.

COMPLICATIONS
- Nonunions, wound healing problems, and loss of correction after surgery may be related to a number of factors.
- Historically, the distal tibia is associated with increased difficulty with both soft and hard tissue healing in the traumatized limb. Also, impaired tissue development and growth due to decreased innervation and physiologic stresses can create a barrier to normal healing.
- Leg-length discrepancy can be seen after opening and closing wedge osteotomies in growing children.
- Delayed union may require prolonged immobilization with weight bearing as tolerated. Nonunion can be managed with improved fixation, autologous bone grafting, and further immobilization in a non-weight-bearing cast.
- Malunion can be due to inadequate fixation or slow healing and loss of fixation.
- Recurrence of the deformity can be due to continued growth with partial physeal arrest.
- Premature growth plate closure can occur with the oblique osteotomy. This can occur as a planned portion of the procedure or can be due to periosteal stripping at the level of the physis or fixation crossing the physis.
- Pseudarthrosis of the fibula can occur after fibular osteotomies. These are most often asymptomatic and can be observed. When painful, open reduction, plate fixation, and bone grafting should be considered.

REFERENCES
DEFINITION
- Children with osteogenesis imperfecta (OI) and syndromes with congenital brittle bones sustain recurrent fractures and deformity, which cause chronic pain and limit their function.\(^{19,20}\)
- Multiple percutaneous osteotomies and percutaneous telescoping intramedullary nailing can improve comfort and function with lower morbidity than previously was possible.
- The severity of bone disease, fracture incidence, degree of deformity, and functional level of the patient, as well as the patient’s response to medical treatment, are more important in surgical decision-making than the specific diagnostic type of OI or brittle bone disease.

ANATOMY
- There is broad variation in anatomic findings in the different types of OI and other brittle bone diseases that resemble it.
- Some children have blue sclera, obvious dentinogenesis imperfecta, triangular facies, and ligamentous laxity, but this varies greatly, even within the same family, and many affected children have none of these findings.
- The defining characteristics of children with OI are a varying degree of bone fragility, and recurrent fractures.
- Progressive anterior bowing of the long bones is quite common, especially in children with moderate to severe involvement, even with early treatment with bisphosphonates ([FIG 1]).
- Coxa vara, both apparent and true, can develop.\(^{8}\)

PATHOGENESIS
- OI is caused in the great majority of cases by dominant mutations in type I procollagen genes.
- In the remaining cases, children may have brittle bone disease with a similar presentation and problems that are not caused by mutations in the type I procollagen genes.\(^{1,19}\)
- The flexors, such as the gastrocnemius muscles and hamstrings, contribute to the progressive bowing.
- Secondary joint contractures may be seen as a result of the longstanding deformities.

NATURAL HISTORY
- Historically, children with very severe OI, especially Sillence type II, rarely survived infancy, and children with types III and IV had severe disability secondary to recurrent fractures, bone pain, and deformities.\(^{24,25}\)
- Before bisphosphonate therapy was available, ambulation and even functional, comfortable sitting were difficult if not impossible for many children with severe forms of OI.
- Even children with less severe forms of OI may have many significant fractures, which inhibit comfort, function, and quality of life.

PATIENT HISTORY AND PHYSICAL FINDINGS
- Findings vary greatly depending on the type and severity of OI. In addition, findings on physical examination may change dramatically as children respond to treatment with bisphosphonates.

FIG 1 • A. Radiographs of an infant with moderately severe osteogenesis imperfecta (OI). B. At 16 months of age, bone strength is improved, but deformity does not remodel.
Possible physical findings include blue sclera, triangular face, dentinogenesis imperfecta, joint laxity, bowing of the arms and legs, and flattening of the skull, especially in infants with severe involvement, but these findings vary greatly even within the same family, and many of the children have none of these classic physical findings.

Flexible flat feet and externally rotated lower extremities are quite common.

A variety of presentations are possible, and children with subtle forms of OI may appear totally normal on physical examination, but present with multiple and recurrent fractures.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Plain radiographs are preferred as the initial study to evaluate children who have or may have OI.
- Full-length radiographs of both legs on the same cassette from the hips to the ankles are ideal to assess areas of fractures and degree of deformity.
- Radiographs of the lower extremity should be performed with the patellas directly anterior and also with the legs maximally externally rotated. This helps assess the severity of the disease, can help predict risk of fracture, and is useful in preoperative planning for osteotomies and instrumentation (FIG 2).
- Standardized posteroanterior (PA) and lateral spine radiographs demonstrate spinal fractures, scoliosis and spondylolysis, and spondylolisthesis.
- Bone density (dual x-ray absorptiometry [DEXA]) scans, although not perfect, can be useful in monitoring changes in bone density, using age-matched Z-scores and consistently using the same techniques and machine type. The DEXA scan alone, however, cannot be used for diagnosis, especially in infants, for whom no standardized validated Z-scores have been established.
- The child’s clinical course with regard to incidence of fracture and pain is a much more reliable indicator of successful medical treatment than a specific Z-score.

**DIFFERENTIAL DIAGNOSIS**

- Child abuse
- Metabolic bone disease (eg, hypo- and hyperphosphatasia, rickets)
- Idiopathic juvenile osteoporosis

**NONOPERATIVE MANAGEMENT**

- Early diagnosis and treatment with bisphosphonates has significantly improved the lives of children with OI. This treatment positively alters the mechanical properties of their bones, decreases their fracture rate and pain, and enhances their psychomotor development.
- This improvement in bone density and strength often allows them to function at levels that previously were not possible by decreasing their bone fragility and pain.
- Surgical treatment for these children is now possible, whereas previously in many cases no surgical options existed because of the severity of their bone disease.
- It has been suggested that treatment with pamidronate may be related to delayed healing of osteotomies—but not fractures—in children with OI.
- It remains unclear whether the incidence of delayed healing will decrease with lower doses of pamidronate.
- Casting, splinting, and bracing for many children with OI should be short-term temporizing measures only, because residual deformities will not remodel, and osteoporosis is worsened by prolonged immobilization.

**SURGICAL MANAGEMENT**

- Intramedullary fixation of long bones in children with OI required extensive soft tissue disruption with traditional techniques.
- Insertion of telescoping and nontelescoping rods still requires extensive exposure and arthrotomies for insertion, and the reoperation rate is high.
- Improved surgical treatment has been made possible by the development of percutaneous techniques, as well as modification of existing nails and development of new nails for fixation, both telescoping and nontelescoping.

**Principles of Surgical Treatment**

- Primary indications for surgical treatment include recurrent fractures, pain, and deformity.
  - These approaches should be considered as children begin attempting to stand or crawl.
  - There is no advantage to waiting until the child is older.
  - Surgical treatment should be considered in acute fracture with deformity, even with less severe OI (FIG 3A,B).
- Correct deformity and axial alignment.
  - Residual bowing does not correct with growth and predictably leads to further fracture.
  - As many involved, symptomatic bones should be corrected at one setting as can be safely accomplished.
- Minimize soft tissue dissection and trauma.
  - Percutaneous technique provides more stability, less scarring, and earlier healing.
- Minimize immobilization.
  - Light splints only
  - Early weight bearing and motion as symptoms allow
  - The role of bracing for long bones is not proven, and bracing may inhibit function.
Part 4 PEDIATRICS • Section III RECONSTRUCTION

**FIG 3** A,B. Plating of the proximal femur in a young child with progressive bowing pain and recurrent fractures at the end of the plate. C. An 8-year-old child treated with an adult nail with lateral migration distally, coxa vara, and proximal growth inhibition. D. The same child treated with the Fassier-Duval nail and valgus osteotomy 6 months postoperatively.

- Use telescoping intramedullary devices whenever possible.
- Use relatively small, flexible nails to share stress.
- Rigid nails may lead to disappearing bone (**FIG 3C,D**).
- Do not remove nails electively.
- Plating predictably leads to stress reaction.
- Indications in forearm are more limited.
- Fixation in the forearm is less predictable, and has higher risks and rate of complications.
- Instrumentation and bone quality are not optimal.

- Such fixation should be considered only when comfort, motion, and function are significantly limited by deformity.

**Preoperative Planning**

- The keys to surgical success are careful selection of children with adequate bone strength and density, and availability of an experienced team and appropriate equipment (**FIG 4A**).
- Templates must be used to ensure that every appropriate size and type of device is available (**FIG 4B**).

**FIG 4** A. Fassier-Duval instrumentation tray. B. Templates for Fassier-Duval nail. (B: Courtesy of Pega Medical, Inc, Montreal, Canada.)
Radiographs can be used to estimate length and diameter of nails as well as to determine osteotomy sites (FIG 5).

**Measuring the Fassier-Duval Nail**
- The distance from the greater trochanter to the distal femoral physis can be used to estimate the length of the female nail.
- The female nail should be approximately 1 cm shorter than this distance.
- Digital software and templates to determine length and diameter of the nails are available.
- Angular correction can also be estimated on digital radiographs, but they can be deceiving because of the multiplanar nature of the angulation.
- The female nail can be cut preoperatively, but I prefer to cut the female nail intraoperatively, after the osteotomies are completed.

**Positioning**
- For fractures and deformities of the tibia and femur, the patient is placed in the semilateral position with an axillary roll and a long, padded posterior roll near the edge of the radiolucent table.
- The leg can be gently rotated from the anteroposterior (AP) to the lateral position with the C-arm positioned on the opposite side of the table (FIG 6).
- Only one leg can be prepped at a time especially if both the femur and tibia are being treated at the same surgical setting.
- Bilateral tibial surgery can be done supine, but not femoral surgery.

**Approach**
- For the femur, a 1.5-cm vertical incision is made, starting at the tip of the greater trochanter and extending proximally (FIG 7A).
- The fascia of the abductors is then incised, exposing the white greater trochanter (FIG 7B).
- The tibia is approached through a medial peripatellar incision, bluntly dissecting behind the patellar tendon when possible without disrupting the synovium. If necessary, an arthrotomy can be used to expose the starting point for the tibial nail just anterior to the tibial spines.
- The humerus is approached through a small deltoid-splitting incision to expose the greater tuberosity.
APPROACHES TO OSTEOGENESIS IMPERFECTA

Percutaneous Osteotomy With Intramedullary Telescop ing Fassier-Duval Nail

- The percutaneous technique described in this section is as described by Fassier and Duval\(^7,8,17\) with only minor technical variations.
- The open technique, which is not described in this chapter, is performed the same way, with the following exceptions:
  - A larger incision at the osteotomy or fracture site
  - Retrograde guidewire placement and reaming of the proximal fragment
  - Passing the wire into the distal femur under direct vision

Guidewire Placement and Osteotomies in the Femur

- Short and long guidewires are available, depending on the length of the femur.
- Ideally, the tip of the guidewire is placed just medial to the center of the greater trochanter.
- It may be difficult to visualize the greater trochanter in small children with poor bone density, and the insertion point may be necessarily in the piriformis fossa to avoid overreaming of the lateral cortex and to allow a straight line of advance to the femoral canal.
- Avascular necrosis has not been demonstrated in children in whom this technique has been used.
- The relation between the entrance point and use of the nail and the development of coxa vara is not clearly defined at this point\(^1\) (TECH FIG 1A).
  - The wire is then advanced to the first osteotomy site.
  - In many cases it is necessary to angle the wire markedly, both anteriorly and laterally, at first because of the very common severe anterior and lateral bowing of the femur in the subtrochanteric region.
  - Osteotomy sites are marked on the skin after visualization with the C-arm, based on preoperative templating and intraoperative visualization (TECH FIG 1B).
  - A 1-cm incision is made directly over the anterior lateral apex of the deformity.
  - Blunt dissection then is performed with a hemostat down to the periosteum (TECH FIG 1C).
  - The periosteum is incised longitudinally with a small osteotome, which is then rotated 90 degrees (TECH FIG 1D).
  - An incomplete osteotomy is performed while stability of the leg is maintained manually. The osteotomy is completed with gentle manual pressure, the guidewire is extended to the next osteotomy site, and the process is continued until all deformities are corrected.
  - The guidewire is then passed into the distal femur (TECH FIG 1E).
  - Use of a longer guidewire can help to avoid capturing the guidewire in the reamer.
  - A subtle flexion deformity often is present distally, in both the femur and tibia, that is not always apparent on the preoperative radiographs and that will cause the nail to go too far anteriorly.

TECH FIG 1 • A. Guidewire placed through the greater trochanter to the site of the first osteotomy. B. Localization for osteotomy. Reaming can be done at the site of the osteotomy to stabilize the proximal segment. C. A 1-cm incision is made over the apex of the osteotomy, and the soft tissues are spread to the periosteum. D. The osteotome is rotated and the osteotomy completed. Gentle manual traction and use of a lever such as a padded mallet will help to gently align and complete the osteotomy site. E. Guidewire in the distal femur.
Reaming and Placement of the Male Nail
- The reamers are 0.25 to 0.35 mm larger than the corresponding nails.
- The canal is reamed over the guidewire down to the distal femoral metaphysis, approximately 1 cm proximal to the physis in the center-center position on both AP and lateral radiographs (TECH FIG 2A).
- The guidewire is removed to insert the male nail driver and nail after verifying the distal male nail thread length, while maintaining traction manually.
  - Avoid bending the rod and driver, to prevent impingement and damage to the nail.
  - The nail and driver cannot be used to forcefully manipulate the osteotomy or fracture site.
- The nail and driver are passed to the center-center position in the distal metaphysis (TECH FIG 2B,C).
- If the male nail requires redirection, it should be retracted slowly, while maintaining a gentle counterclockwise screwing motion to prevent dislodgment of the driver from the wing of the nail, which is not locked in the male nail driver (TECH FIG 2D).
- On occasion, it may be necessary to remove the male nail and repeat the process.
- Varus and valgus malalignment can be corrected with a distal osteotomy and correct placement of the nail in the center-center position in the distal femur.
- Correct positioning is checked using AP and lateral views with the C-arm just before passing the male nail across the center-center position of the physis.
- The threads are gently screwed into the epiphysis until the rounded portion of the rod located just proximal to the threads is bridging the physis.
- Multiple transgressions of the physis are to be avoided.
- The rod pusher is then placed into the cannulated portion of the male nail driver, and a sharp backward blow is made on the T handle. The C-arm verifies that the male nail is still engaged in the epiphysis (TECH FIG 2E).

Cutting and Insertion of the Female Nail
- To measure the length of the female rod intraoperatively, it is placed with the threaded portion just at the top of the ossified greater trochanter with C-arm verification using a metal marking device distally approximately 1 cm above the physis (TECH FIG 3A).
- The appropriate length of the female nail is verified with the C-arm, as previously discussed.
- The female nail is covered with K-Y Jelly (Johnson & Johnson, New Brunswick, NJ) then cut with a diamond-tip burr and cooled with sterile saline.
- The cannulated portion must be checked to ensure that no metal will impinge on the male nail to prevent it from lengthening and that any metal shards are rinsed off (TECH FIG 3B,C).
- The male nail driver is then removed, and the female nail is placed over the male nail.
- The female nail is then screwed into the greater trochanter with the T-handle screwdriver until just a few threads are engaging the bony portion of the greater trochanter, and the upper part of the female nail is just palpable above the greater trochanter (TECH FIG 3D).
- If the female nail is too shallow, it will back out, but if it is too deep, it is more likely to become overgrown and ultimately reside in the femoral canal.
The female nail is checked distally to be sure there is some space between its distal end and the wing of the male nail, to ensure that the male nail is not driven distally into the joint either acutely or with impaction of the osteotomy with weight bearing (TECH FIG 3E,F).

The male nail can be cut either with a front-biting heavy wire cutter or with the male nail cutters in the FD set.

Cutting the male nail approximately 1 cm above the top of the female nail rarely causes persistent symptoms and allows for more growth.

The probe is used to ensure that the cut male nail is smooth and not bent, which would prevent telescoping.

Occasionally, the diamond-tipped burr may be necessary to smooth the end of the male nail, but the soft tissues must be protected from debris and injury.

**Coxa Vara**

If true coxa vara is present, it should be corrected at the same sitting by combining this femoral nail technique with the valgus osteotomy described by Fassier and Glorieux® (TECH FIG 4).

**Revision**

When a rod system requires revision after maximal telescoping, it usually can be retrieved through just a proximal incision.

A guidewire is placed in the greater trochanter and into the cannulated portion of the female nail under fluoroscopic control.

Specialized female and male retrievers, as shown, allow for intramedullary retrieval (TECH FIG 5).
Open osteotomy, cutting the rod and removing the segments, may be necessary to retrieve a broken or bent nail or one that has migrated laterally and distally. The male nail also may be retrieved with an arthroscopic alligator clamp after the female nail is removed.

**Tibial Technique**

- Nails from the small-bone set are used. These have a somewhat shorter female-threaded portion to avoid extension of the threads across the proximal tibial epiphysis.
- Injury to the anterior horn of the medial meniscus is avoided with arthrotomy if necessary.
- A 0.62-inch K-wire or awl is placed just lateral to the anterior horn of the medial meniscus, and just anterior to the tibial spine in the non-weight-bearing surface. A soft tissue protector is helpful in directing the guidewire.
- This usually places the wire in the midportion of the tibial epiphysis on the AP view and at the junction of the anterior and middle thirds on the lateral view.
- With the knee kept flexed in excess of 90 degrees, the guidewire is passed into the center position of the proximal metaphysis and shaft.
- Typically, the wire tends to go posteriorly and laterally so that the wire driver must be directed anteriorly and usually slightly medially.
- Alternatively, the wire can be manually pushed into the epiphysis if this provides better control and visualization with the C-arm.
- Avoid repetitive injury to the physis by checking the direction of the wire with the C-arm while it is still in the proximal tibial epiphysis. The guide pin can be advanced either with manual pressure on the pin or using a drill.
- While maintaining hip and knee flexion, the lateral radiograph can be done by simply abducting and externally rotating the leg.
- The guidewire is drilled down to the site of the first osteotomy, which often is the mid- to distal portion of the shaft of the tibia, although bowing of the proximal tibia also may be present.
- To perform the tibial osteotomy, a 1.5-cm incision is made. The periosteum is visualized and partially elevated. Multiple osteotomies may be necessary (TECH FIG 6A).
- A pure closed technique is more hazardous in the tibia.
- When the medullary canal is obliterated by recurrent fracture and bowing, retrograde drilling is required to establish a medullary canal at the osteotomy site.
The guidewire is then passed beyond the osteotomy.
Ideally, the entrance point to the distal tibial epiphysis is slightly posterior on the lateral view and slightly lateral on the AP view. This helps to avoid the tendency to valgus and anterior cut-out.
Closed osteoclysis of the fibula often can be performed with minimal force after the first osteotomy, especially in younger children, but open osteotomy may be necessary.
The reamer is passed down to the distal metaphysis while maintaining the knee in flexion at all times.
Reaming should be done slowly, with frequent stops at the apex of the angular deformity. This bone typically is quite dense in response to recurrent fractures.
Extending the knee while the reamer is in place can impinge and injure the femoral condyles.
The male nail is either cut after determining the length with the C-arm before placement into the tibia, which is my preferred technique, or inserted, removed, and then cut after the appropriate length is determined (TECH FIG 6B,C).
There is a small hole in the distal male nail to allow interlocking with a small wire, which is then bent over into the epiphysis. I have not used this technique and have concerns about migration and retrieval of the wire with growth.
The female nail is cut to length in the same manner as for the femoral technique, and inserted until the threaded portion is fully seated into the epiphysis.
It usually is visible just a few millimeters deep to the articular cartilage, even when the C-arm suggests that it is protruding into the joint (TECH FIG 6D,E).

Humeral Nailing
The deltoid is spread in line with its fibers through a 1.5-cm incision, and the greater tuberosity is exposed.
The guidewire is drilled down into the shaft.
Typically, the diaphyseal deformity involves the mid- to distal shaft of the humerus when the guidewire is passed to the apex of angular deformity.
If a proximal deformity is present, an open or percutaneous osteotomy can be considered.
A distal anterolateral approach is used, and the radial nerve is identified and protected before the distal osteotomy is done.
The guidewires are then drilled down into the ossified capitellum after correction of the varus and anterior bowing.
The canal is then reamed to the size of the female nail down to the distal metaphysis.
The male nail is then placed down into the capitellum, which commonly leaves a slight amount of varus, which is well tolerated (TECH FIG 7A).
In older children, the nail can be placed into the superior segment of the ossified central trochlea, which allows better correction of the distal varus.
The small-bone female nail is used, cut to appropriate length before insertion. The upper end of the female nail should be deep to the articular cartilage to avoid impingement. This is verified by placing the shoulder through full range of motion (TECH FIG 7B–C).

![TECH FIG 7 • A,B. AP and lateral male nail in capitellum. C. Female nail appears to be protruding but is actually deep to the articular cartilage and is not causing impingement. D. Two years postop. Note telescoping of nail. There is no clinical impingement.](image-url)

Adequate analgesia upon awakening is necessary to avoid flailing and fracture.
Treatment with Valium is significantly beneficial for spasm.
Many children have high narcotic requirements for a short period of time when multiple exposures have been done.

Revisions are still necessary as the children outgrow or damage the rods, but the instrumentation allows for a less traumatic experience for the patient and surgeon.

Complications include failure of telescoping of the rod, overgrowth of the greater trochanter, bending and breakage of the rods, as well as delayed union and nonunion.
Treatment for symptomatic complications of the rod is revision.
Fractures can occur even with satisfactory alignment, but recovery is typically rapid and requires short-term restriction of activities rather than long-term immobilization.

Postoperative Care

- Postoperative immobilization can be accomplished safely with lightweight radiolucent fiberglass wrapped under the foot to resist equinus and avoid heel pressure.
- The splint can be extended up to the buttocks to support the femur, and loosely overwrapped with an elastic wrap.
- Rarely, a percutaneous tendo Achilles tenotomy will be required.
- Floor activities can be increased whenever the child is comfortable.
- Weight bearing can begin in water approximately 4 weeks after the osteotomies achieve early healing and rotational control.
- Gentle passive range of motion of the hips, knees, and ankles can begin as soon as the child is comfortable.
- Hip, knee, ankle, and foot orthoses are a time-honored treatment and are used postoperatively in many centers.
  - Their effectiveness in avoiding recurrent fractures and deformity has not been demonstrated, however, and we do not use them in our center.
  - Many of the children are significantly more mobile without these orthoses, and healing is not impaired.
  - I prefer to limit use of orthoses to only those children with significant soft tissue laxity in the feet such that support is required for stability.

Outcomes

- Improved comfort, a decreased rate of fracture, and an increased activity level are achieved in most children.
- Long-term monitoring of these patients and constant improvement in instrumentation are necessary to ensure optimal development, comfort, and function in this patient population.

References

DEFINITION
- Fibular deficiency, previously known as fibular hemimelia, is a longitudinal deficiency of the fibula. It is the most common long bone deficiency and may be either partial or complete.
- A wide spectrum of associated anomalies also may be seen on the affected limb. The extent of limb shortening and the degree of foot deformity are the most important components that determine treatment. Treatment options include use of a shoe lift, amputation, and limb lengthening.
- Delayed amputation should be avoided whenever possible. Ideally, amputation is performed at 10–18 months of age when the child is beginning to pull to stand. Psychosocial adjustment to amputation and the adjustment to prosthetic wear are rapid at this age.
- A common dilemma for parents and consulting physicians is an unwillingness to commit to a path of either multiple lengthenings or early amputation. It is generally agreed, however, that the least effective approach to fibular deficiency is “let’s try lengthening and if it fails, do an amputation.”
- The Syme amputation and the Boyd amputation are the two common amputations performed for fibular deficiency.
- The Syme amputation is an ankle disarticulation that preserves the heel pad as a weight-bearing surface. This procedure provides better energy efficiency than a transtibial amputation, may be self-suspending, allows weight bearing on the stump without the use of a prosthesis, and is cartilage capped, preventing terminal overgrowth.
- The Boyd amputation is a modified ankle disarticulation in which the calcaneus is preserved with the heel pad and fused to the distal tibia.
- The best indications for an amputation are a large leg-length discrepancy (ie, a difference of more than 30%) at skeletal maturity and a nonfunctional foot.
- The ideal candidate for lengthening has a smaller expected leg-length discrepancy (less than 10%), a stable ankle, and a fully functional foot.
- Because both amputation and multiple lengthenings have significant consequences, care must be individualized. This is especially important for patients with leg-length discrepancies between 10% and 30%, for which both amputation and lengthening have been shown to be effective with excellent functional outcomes.

ANATOMY
- Fibular deficiency is best considered an abnormality that affects the entire limb, not just the fibula (FIG 1A).
- The appearance of the leg can vary from nearly normal to severely deformed (FIG 1B).
Potential ipsilateral deformities associated with fibular deficiency are as follows:
- Femur: mild femoral shortening, femoral retroversion, lateral femoral hypoplasia
- Knee: cruciate ligament deficiency, valgus alignment, patella-femoral instability
- Tibia: shortening, anteromedial diaphyseal bowing
- Ankle: ankle valgus, absent lateral malleolus, ball-and-socket ankle
- Foot: absent tarsal bones, tarsal coalitions, absence of one or more lateral rays

The amount of fibula present does not aid treatment planning. For example, some patients with complete fibular absence have minimal leg-length inequality and foot deformity.

An understanding of the anatomy of the ankle and heel is necessary to perform either the Syme or Boyd amputation procedure.

The posterior tibial nerve and artery course posterior to the medial malleolus and split into the medial and lateral plantar nerves. These structures must be protected for the heel pad to maintain its sensation and viability.

**PATHOGENESIS**

Unlike tibial deficiency, fibular deficiency occurs sporadically with no inheritance pattern.

No genetic defect has been identified, and no common teratogen is linked to fibular deficiency.

Major limb malformations associated with fibular deficiency occur by the 7th week of fetal development.

**NATURAL HISTORY**

Without surgical intervention, the growth of the abnormal limb remains proportional to the normal side. Therefore, a final leg-length discrepancy is predictable.

For example, if the short leg is 85% the length of the long side at age 2 years, the length of the short side at maturity also will be 85% of the estimated length of the long side at maturity.

Tibial bowing is present in most cases of complete absence of the fibula. In some cases this bowing will improve with age.

Unlike anterolateral bowing of the tibia, bowing associated with fibular deficiency does not increase the risk of fracture or pseudarthrosis.

Knee valgus commonly worsens through childhood. It may require surgical treatment when prosthetic modifications are inadequate to compensate for the deformity.

**PATIENT HISTORY AND PHYSICAL FINDINGS**

Classically, the limb is short, with an equinovalgus foot and skin dimpling over the mid-anterior tibia.

Because presentation varies widely, an examination to assess length, alignment, and function is critical to treatment.

Hip range of motion: a common finding is limited internal rotation (less than 20 to 60 degrees), indicating femoral retroversion.

Leg-length assessment: there should be minimal shortening of the thigh. Otherwise, consider proximal femoral focal deficiency. Small leg-length discrepancies can be corrected with a shoe lift or lengthening.

Lachman’s test: severe anterior/posterior laxity increases the risk of subluxation during lengthening.

Valgus alignment and stability: small angulation is accommodated through prosthetic adjustment, but larger angulation requires correction.

Tibial bowing requires prosthetic adjustments or correction.

Ankle alignment and stability: amputation is preferred over lengthening when severe subluxation or instability exists.

Hindfoot mobility: suspect tarsal coalition if subtalar motion is reduced.

Ray deficiency (number of missing rays): amputation is indicated when the foot is nonfunctional.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

Anteroposterior (AP) and lateral radiographs of the leg (including the distal femur) should be obtained.

Absence of the anterior cruciate ligament and hypoplasia of the lateral femoral condyle with a valgus joint alignment are common (FIG 2A, B).

The amount of anterior bowing (tibial kyphosis) also can be assessed (FIG 2C).

Additional radiographs of the affected limb (ie, femur, ankle, and foot) are obtained as necessary (FIG 2D).

A full-length standing radiograph from hips to ankles should be obtained to check alignment in those children able to stand (FIG 2E).

A scanogram and bone age should be obtained to determine the expected leg-length discrepancy at maturity.

The desired limb-length difference at maturity should be at least 3.5 cm to accommodate the height of the prosthetic foot. Epiphysiodysis may be necessary to achieve this and should be planned appropriately.

An ankle and foot series should be obtained when abnormal position or motion is present at the ankle or subtalar joint or when lateral rays are absent. These views may reveal a ball-and-socket ankle (FIG 2F), tarsal coalitions, or absent or hypoplastic tarsal bones (FIG 2G).

**DIFFERENTIAL DIAGNOSIS**

- Proximal femoral focal deficiency
- Tibial deficiency
- Tibial dysplasia

**NONOPERATIVE MANAGEMENT**

- If the leg-length discrepancy is small, the ankle is stable, and the foot is plantigrade, a shoe insert or lift may be all that is required.
- When amputation or lengthening is needed but must be deferred, an atypical prosthesis that accommodates the foot position can be used.

**SURGICAL MANAGEMENT**

**Syme Amputation**

- Meticulous care is needed to preserve the posterior tibial nerve and vessels to maintain a sensate stump.
- Care should be taken not to leave any cartilage remnants of the calcaneus during resection.
- The malleoli should not be resected in children.
- The heel pad may be proximal to the ankle joint and can be difficult to bring distally, even after sectioning the Achilles tendon.
The Pirogoff modification maintains a portion of the calcaneus, which is fused to the distal tibia to better fix the heel pad. Because in young children the distal tibial physis must be resected to obtain fusion of the calcaneus to the tibia, this is really a modification of the Boyd amputation, since distal growth of the tibia will be lost.

**Advantages**
- Simple technique
- Rapid prosthetic fitting
- The stump is shorter and often tapered, which improves cosmesis (but also may inhibit end-bearing)

**Disadvantages**
- Heel pad migration (FIG 3)
- Less end-bearing potential

**Boyd Amputation**

**Advantages**
- Maintains maximum length of limb
- Eliminates heel pad migration
- Flare at the end of the stump improves prosthetic suspension
- Maximizes end-bearing potential. This may be especially important if it preserves end-bearing without a prosthesis (eg, not having to put on a prosthesis to go from the bed to the bathroom).

**Disadvantages**
- Delays prosthesis fitting by several weeks while awaiting fusion

![FIG 2 • A,B. AP and lateral radiographs of a child with fibular absence, hypoplasia of the lateral femoral condyle, and anterior cruciate deficiency. C. Anterior bow of the tibia. D. AP radiograph of the same patient’s foot, revealing severe equinovarus deformity and talocalcaneal fusion. E. Standing AP radiograph of a child with proximal femoral focal deficiency revealing a substantial leg-length discrepancy and abduction of the affected limb. F. Ball-and-socket ankle. G. Nonfunctional foot with hypoplastic tarsal bones, tarsal coalition, and absent rays. (E: Courtesy of Hugh Watts, MD.)

![FIG 3 • Posterior heel pad migration after Syme amputation.]
Excess length may leave less room for energy-storing prosthetic foot options, and the bulbous end may be difficult to hide if it is at the level of the opposite ankle.

Preoperative Planning

**Syme Amputation**

- In patients where the tibial length at skeletal maturity is expected to be equal to that of the opposite side, a Boyd amputation or timed epiphysiodesis should be considered to accommodate the height of the prosthetic foot to achieve equal limb lengths at maturity.
- It usually is not necessary to correct mild bowing (less than 30 degrees) of the tibia in a congenital deficiency in a skeletally immature patient. Bowing of more than 30 degrees should be addressed with osteotomy at the time of amputation.

**Boyd Amputation**

- If anterior tibial bowing is present, it is best to correct it at the same time as the Boyd amputation.
- The tarsal bones and distal tibia epiphysis are primarily cartilaginous in infancy.
- If a Boyd amputation is performed early, it will be necessary to resect a significant portion of the superior calcaneus and distal tibia to achieve bone–bone contact for fusion.
- If maximum length of the tibia is a goal of treatment (eg, to allow occasional end-bearing on the stump end without a prosthesis), consider waiting until the distal tibia epiphysis is ossified adequately to avoid resecting the distal physis.
- Some authors have suggested that routine resection of the distal tibia physis should be performed.

They observed that most children stop walking around the house without a prosthesis in early adolescence and that ideally the short limb should end in the middle fifth of the shank segment of the prosthesis to optimize cosmesis and allow room for a dynamic-response foot-and-ankle unit.²

**Positioning**

- The patient is positioned supine with a small bump under the greater trochanter. A tourniquet is placed around the upper thigh.
- Access to the entire leg from knee to toes is important (FIG 4).

**AMPUTATIONS FOR FIBULAR DEFICIENCY**

**Syme Amputation**

**Incisions**

- The dorsal incision is made at the tip of the lateral malleolus (or where it should be) across the ankle joint to end about 1 cm below the tip of the medial malleolus.
  - In children with congenital fibular absence, the lateral malleolus is not present, and the end of the first incision must be approximated.
- The Achilles tendon (often very tight in patients with congenital fibular absence) can be released through a separate, percutaneous incision posteriorly to improve exposure.
- The plantar incision is made at the midportion of the metatarsals and carried proximally up the medial and lateral sides of the foot to meet the anterior incision (TECH FIG 1).
  - The plantar incision can be cut directly down to bone, with care to be sure that the knife blade remains perpendicular to the skin. Vessels are ligated or cauterized.

**Amputation**

- The foot is now plantarflexed (TECH FIG 2A). The anterior incision is deepened down to bone, again keeping the knife perpendicular to the skin.
- The anterior ankle joint is opened, and the deltoid and tibiofibular ligaments are cut sharply, with care not to injure the posterior tibial nerve and artery coursing behind the medial malleolus.
- The foot is further plantarflexed to expose the posterior ankle joint, which is released, exposing the posterior calcaneus and the Achilles tendon.
- A bone hook or sharp retractor can be used to pull on the talus distally as the posterior joint is opened (TECH FIG 2B).
- The calcaneus is now released from the heel pad extraperiosteally. Care is taken not to separate the calcaneal apophysis from the body of the calcaneus.
- The Achilles tendon is now sectioned.
  - In very tight equinus, the Achilles can be released through a percutaneous incision posteriorly.
  - Once the tendon is easy to visualize, a 1-cm section of the tendon should be removed to prevent late migration of the heel pad.
- The tourniquet is deflated, and perfusion of the heel pad is checked and bleeding is controlled (TECH FIG 2C).
- The distal tibial cartilage and malleoli are left intact.
  - A Steinmann pin or Rush rod may be inserted through the heel pad into the distal tibia to affix the heel pad to the distal tibia (TECH FIG 2D).
**Chapter 38  SYME AND BOYD AMPUTATIONS FOR FIBULAR DEFICIENCY**

**TECH FIG 1**  •  A. Incisions for the Syme amputation. B. Medial incision and identification of the posterior tibial artery and nerve. (B: Courtesy of Hugh Watts, MD.)

**TECH FIG 2**  •  A. The foot is plantarflexed while the dorsal incision is completed. B. A retractor is placed in the talus to expose the posterior capsule and Achilles tendon. C. Intraoperative photograph after deflation of the tourniquet, illustrating a well-perfused heel pad. D. Stump closure with interrupted absorbable sutures after insertion of a Steinmann pin to stabilize the heel pad. (Courtesy of Hugh Watts, MD.)
**TECH FIG 3** • **A, B.** The dorsal and volar parts to the fish-mouth incision meet medially and laterally just distal to the malleoli. **C.** The plantar incision crosses the foot just distal to the heel pad.

**TECH FIG 4** • **A.** The plantar incision is carried down to the bone. **B.** Dorsal structures are transected with the foot in plantar flexion. **C.** Use the forefoot to control the hindfoot. **D, E.** Release the deltoid and lateral capsule. **F, G.** Carefully divide the posterior capsule and remove the talus. **H, I.** Sometimes the talus is small and irregularly shaped, as seen in this case, in which the L-shaped talus hooked around the back of the distal tibia.
Closure is done over a drain using interrupted sutures.
- In young children, an absorbable suture is used to avoid later removal.
- An antibiotic-impregnated gauze is applied followed by fluffs and Webril.

**Boyd Amputation**

**Incision and Dissection**
- A fish-mouth incision is made (TECH FIG 3).
  - The plantar incision crosses the foot where the heel pad ends.
  - The dorsal incision crosses the foot at the level of the ankle joint.
  - The incisions meet medially about 1 cm distal to the medial malleolus and laterally in a similar location (the lateral malleolus often is absent in fibular deficiency).

**Midfoot and Forefoot Removal**
- It is unnecessary to dissect layer by layer on the plantar side. Instead, sharply deepen the plantar incision down to the level of the bone (TECH FIG 4A).
  - Vessels can be ligated or cauterized (depending on their size) as they are cut or after the tourniquet is deflated before closure.
- While maximally plantarflexing the foot, transect the dorsal nerves and extensor tendons, which retract proximal to the incision (TECH FIG 4B).
- Do not remove the midfoot and forefoot at this time. They can serve as a handle to control the hindfoot when releasing the tibiotalar capsule and ligaments (TECH FIG 4C).
- Expose the tibiotalar joint by releasing the anterior capsule and then release the deltoid ligament medially and the talofibular ligament with the lateral capsule (TECH FIG 4D,E).
  - Use care to preserve the posterior tibial artery and vein while dividing the posterior ankle capsule.
  - A bone hook or skin rake on the talar dome will help expose the posterior tibiotalar capsule and Achilles tendon.
- Identify the flexor hallucis tendon and protect the neurovascular bundle that lies just medial to the tendon (TECH FIG 4F).
- Remove the talus after cutting through the talocalcaneal ligaments (TECH FIG 4G).
- Removing the talus may be more difficult in the very young child, in whom the talus is primarily cartilaginous, or when it has an irregular shape (TECH FIG 4D,E).
- The midfoot and forefoot are now removed.

**Completing the Amputation**
- Use an oscillating saw (or, in very young children, a knife) to remove the anterior process of the calcaneus and enough of the superior articular surface to expose cancellous bone (TECH FIG 5A–C).
- Cut the distal tibia (TECH FIG 5D).
- Oppose the cancellous bone surfaces and stabilize with a retrograde K-wire placed through the heel pad and across the tibiocalcaneal surfaces (TECH FIG 5E,F).

**Correction of Tibial Bowing**
- Make a longitudinal anterior incision at the apex of the bowing.
- Expose the tibia subperiosteally and place Chandler or Hohmann retractors to protect the soft tissues.

**TECH FIG 5 • A–C.** Prepare the calcaneus by cutting the anterior and dorsal surfaces. **D–F.** Stabilize the calcaneus to the end of the tibia with a smooth K-wire.
POSTOPERATIVE CARE

- Apply a long-leg cast with the knee flexed 90 degrees to prevent pin migration and keep the cast from slipping off.
- Postoperatively, the patient’s leg is elevated for 24 hours.
- The child should be non-weight bearing.
- The cast and pin are removed in the office at 4 to 6 weeks, and, in the Boyd amputation, after radiographic healing is evident (FIG 5A).
- A stump wrap or shrinker is then applied.

PEARLS AND PITFALLS

<table>
<thead>
<tr>
<th>Procedure</th>
<th>Pearls and Pitfalls</th>
</tr>
</thead>
<tbody>
<tr>
<td>Calcaneus excision (Syme)</td>
<td>Remove the calcaneus extraperiosteally. This requires careful dissection but decreases the chance of reformation of the calcaneus. Any residual calcaneal cartilage left will result in painful pebbles of bone in the heel pad.</td>
</tr>
<tr>
<td>Tibial bowing (kyphosis)</td>
<td>Correct at the time of amputation if greater than 30 degrees, and fix with the transfixing Steinmann pin or Rush rod.</td>
</tr>
<tr>
<td>Achilles tenotomy</td>
<td>The Achilles tendon often is contracted and may make exposure of the calcaneus difficult. A percutaneous release posteriorly with a small tenotomy knife may make exposure easier without compromising the flap.</td>
</tr>
<tr>
<td>Talus excision (Boyd)</td>
<td>Carefully assess the position and shape of the talus and calcaneus to ensure abnormalities of the talus and calcaneus are known in advance. In rare cases, a Boyd amputation will not be possible because of the severe posterior and proximal position of the calcaneus. If so, perform Syme amputation.</td>
</tr>
<tr>
<td>Tibiocalcaneal fusion</td>
<td>Carefully ensure that cancellous bone is evident on both the distal end of the tibia and the superior surface of the calcaneus.</td>
</tr>
<tr>
<td>Skin closure</td>
<td>The distal extent of the heel pad is difficult to identify in children who are not yet walking. Be sure the plantar part of the incision is distal enough to allow closure without tension. Cut the anterior process of the calcaneus to reduce the anterior prominence and skin tension.</td>
</tr>
<tr>
<td>Angular deformities of leg</td>
<td>Correct tibial deformity early to facilitate prosthetic fitting. Correct progressive genu valgum late (ie, in adolescence).</td>
</tr>
</tbody>
</table>

OUTCOMES

- McCarthy et al reported on a comparison of amputation versus lengthening in the treatment of fibular hemimelia.
- Patients undergoing amputation were more active, had less pain, were more satisfied, and had fewer complications than those undergoing limb lengthening.
Fulp et al. reviewed 25 patients (31 extremities) with longitudinal deficiency of the fibula treated with either Syme amputation or Boyd amputation.

- Patients undergoing Syme amputation had more problems with prosthetic suspension, reformation of the calcaneus, and migration of the heel pad.
- Late progressive genu valgum deformity requiring a stapling or osteotomy of the distal femur occurs in 29% to 58% of cases.

**COMPLICATIONS**

- Wound slough/dehiscence
- Migration of the heel pad
- Penciling of the distal tibia
- Infection
- Pin migration
- Nonunion
- Excess length

**REFERENCES**

DEFINITION

- Ankle valgus is a lateral and upward slope of the tibiotalar joint resulting in foot pronation and sometimes lateral translocation of the talus relative to the tibia.
- In the anteroposterior (AP) plane, the weight-bearing axis and ground reaction force fall lateral to the virtual center of the joint. This may perpetuate the cycle of growth inhibition and progressive valgus.

ANATOMY

- Normal alignment of the ankle involves a horizontal plafond, with a lateral distal tibial angle of 0 to 3 degrees (FIG 1).
  - Accordingly, the fibula normally bears 15% of body weight.
  - The talus lies sandwiched between the malleoli, stabilized by the deltoid ligament medially and the talofibular and calcaneofibular ligaments laterally.
  - In the growing child, the fibular physis lies at or distal to the plafond.
  - The physes and plafond lie parallel to the floor and perpendicular to the ground reaction forces.

PATHOGENESIS

- The common denominator of ankle valgus is a fibula that is relatively foreshortened and fails to buttress the lateral tilt and shift of the talus during weight bearing.
  - As the fibular epiphysis bears more than the customary 15% of body weight, it may expand owing to the Hueter–Volkmann effect (another example of form following function).
  - As the ground reaction force is displaced laterally, the compression of the lateral distal tibial physis exceeds its tolerance and inhibits normal growth, not only of the physis, but of the epiphysis as well (Hueter–Volkmann effect).
  - There may be widening of the medial clear space due to attenuation of the deltoid ligament.
  - Subject to chronic and unremitting medial tension, there may be delayed or fragmented osseousization of the medial malleolus.
  - The physes remain horizontal and perpendicular to gravity.
  - With lateral tilt of the talus, shear forces are introduced and articular cartilage attrition may ensue, commencing at the lateral corner of the ankle.
  - Subtalar valgus alignment or instability may develop and exacerbate the clinical deformity.
  - Concomitant genu valgum imposes an eccentric load on the ankle and may compound the alignment problems (hereditary multiple exostoses, clubfeet; FIG 2).

NATURAL HISTORY

- The natural history of ankle valgus typically is insidious and progressive. It may be noticed around school age and becomes self-perpetuating.
  - The natural history is unaffected by corrective shoes or bracing (FIG 3).
  - In some conditions (spina bifida, cerebral palsy), there may be skin breakdown over the medial malleolus with attempts to control valgus by bracing.
  - Left unattended, the ultimate method of salvage may require a supramalleolar osteotomy.
  - This can be avoided by means of medial malleolar epiphysiodesis using a transmalleolar screw or an eight-plate (FIG 4).

PATIENT HISTORY AND PHYSICAL FINDINGS

- Typically the parents have noted chronic, progressively flat or pronated feet.
  - Asymmetric and accelerated shoewear is common.
  - Activity-related pain is typically lateral, beneath the fibula, as a result of impingement on the talus or calcaneus.
  - There may be medial pain, presumably due to tension on the deltoid ligament or to brace irritation.
  - Concomitant knee or hindfoot valgus will exacerbate the symptoms.
While orthotics may provide support, they will have no beneficial effect. As the deformity progresses, brace tolerance diminishes.

The clinician should observe the patient’s stance from the hindfoot position.

The patient’s knee alignment is observed. Genu valgum or circumduction gait exacerbates hindfoot loading.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Radiographs
  - Weight-bearing AP and lateral views of the ankles
  - Weight-bearing AP lateral of the feet to assess subtalar alignment
  - Weight-bearing AP of the lower extremities, if there is perceived valgus or varus deformity of the knee
- EMED foot pressure studies (optional)
- CT scan or MRI if a distal tibial physeal bar is suspected
- CT scan of the foot if a concomitant tarsal coalition is suspected

**DIFFERENTIAL DIAGNOSIS**

The deformity is often bilateral: some of the conditions that are known to result in progressive ankle valgus include the following.

- Neuromuscular
  - Cerebral palsy
  - Spina bifida
  - Neurofibromatosis
- Hereditary—growth
  - Hereditary multiple exostoses
  - Multiple epiphyseal dysplasia
- Genetic
  - Down syndrome
  - Other syndromes
- Traumatic
- Clubfoot
- Idiopathic

The underlying diagnosis (see above) has often been established, but the underlying cause has little relevance to the
treatment. The degree of deformity and the evolution of symptoms dictate the timing and need for intervention.

**NONOPERATIVE MANAGEMENT**
- Activity restriction and nonsteroidal anti-inflammatories are not helpful.
- Physical therapy remedial exercises are of no benefit.
- Soft orthoses or UCB inserts are temporizing means of reducing foot discomfort and extending shoewear.
  - They are relatively more efficacious for subtalar instability than ankle valgus.
  - They will not effect any growth modulation or improvement in skeletal alignment, however.

**SURGICAL MANAGEMENT**
- The indications for surgery relate to the evolution of activity-restricting pain.
- Valgus may be manifest in children under age 10 but is more prevalent during the adolescent growth spurt.
- Many patients have already exhausted nonoperative options, such as shoewear modifications, nonsteroidal anti-inflammatories, and activity restriction.

**Preoperative Planning**
- Both the clinical examination and appropriate weight-bearing radiographs should verify the presence and magnitude of valgus deformities, not only of the ankles but also (occasionally) of the hindfeet and knees as well.
  - In specific conditions, multilevel surgery may be indicated.
  - When the cause involves neuromuscular conditions, concomitant muscle imbalance may warrant combined procedures such as gastrocnemius recession or tendon transfer.
  - When available, a pedobarograph may be useful for documenting pathologic foot stresses.

**Positioning**
- The patient is positioned supine on the operating table.
- The mini or standard C-arm may be used.
- Calf or thigh tourniquets are optional, at the discretion of the surgeon.

**Approach**
- For a transmalleolar screw, a 5-mm transverse incision below the tip of the medial malleolus will suffice.
- For plate correction, a vertical 12-mm incision over the medial distal tibial physis is optimal.
  - The dissection is subcutaneous, with preservation of the peristeam.
  - The only nearby neurovascular structures are the saphenous nerve and vein. These are anterior to the incision and easily avoided.
  - Supramalleolar osteotomy is the option of last resort.

**MEDIAL MALLEOLAR SCREW HEMIEPIPHYSIODESIS**
- With the patient supine and a calf tourniquet inflated (optional), the tip of the medial malleolus is palpated and a 5-mm transverse incision is marked.
- The subcutaneous tissues may be injected with 0.25% Marcaine.
- The incision is made sharply and deepened with a hemostat, spreading the subcutaneous tissues down to the tip of the malleolus.
- A vertical 1.6-mm guidewire is driven upward, with care taken to avoid the ankle mortise.
  - Its trajectory should be vertical, so that the screw will be just lateral to the medial cortex.
  - The more peripheral the fulcrum, the more efficient and rapid the correction will be.
- The C-arm is used to check the guidewire placement in the AP, mortise, and lateral projections.
- The tip of the malleolus is drilled with a 3.2-mm cannulated drill bit and a single 4.5-mm cannulated, fully threaded, cortical screw 40 to 50 mm in length is inserted (no washer is necessary; **TECH FIG 1**).
- The guidewire is removed and the screw should be tightened so that the screw head is not prominent. However, if the head is buried, the screw may be hard to retrieve in the future.
- The wound is closed with 4-0 Monocryl sutures and covered with Steri-Strips, OpSite, and an Ace bandage.

**TECH FIG 1**
- **A.** Transphyseal cannulated 4.5-mm screw insertion is performed percutaneously over a 1.6-mm guide pin for accuracy. The ideal fulcrum is near the medial cortex of the tibia for maximal angular correction. Screw removal is facilitated using the guide pin to seat the screwdriver. **B.** The growth line (arrows) indicates the angular correction achieved to restore a horizontal plafond. Note the downward slope of the physis and the slight bend in the screw, consequent to the intra-physeal fulcrum and the considerable forces of growth on a rigid implant.
GUIDED GROWTH USING AN EIGHT-PLATE

- With the patient supine and under tourniquet control, the distal medial tibial physis is identified using the image intensifier.
- A 12-mm incision is marked in the skin and (optionally) injected with 0.25% Marcaine.
- The incision is made sharply, carrying the dissection through the subcutaneous tissues, with care taken to avoid injury to the periosteum (TECH FIG 2A).
- A Keith needle is inserted into the physis and its position is checked with the C-arm (TECH FIG 2B).
- A 12-mm eight-plate is inserted, placing its center hole over the needle, and applied extraperiosteally (TECH FIG 2C).
- 1.6-mm smooth guide pins are inserted, first into the epi-physesis and then the metaphysis, avoiding the ankle joint and physis (TECH FIG 2D).
- The cortex is drilled to a depth of 5 mm using the cannulated 3.2-mm drill.
- Fully threaded, cannulated screws are then inserted (TECH FIG 2E). For the ankle, the 16- or 24-mm screws may be used. There is no particular advantage to the short (16-mm) screw, but sometimes there is not sufficient room for the 24-mm one. The screws do not have to match or to be parallel.
- After the plate and screw positions are confirmed on the AP and lateral views, the guide pins are removed and the screws are countersunk into the plate (TECH FIG 2F).
- After routine wound closure, a soft compression dressing is sufficient.

TECH FIG 2 • A. For the eight-plate technique, a 12-mm medial incision is made, preserving the periosteum. B. The physis is localized with a Keith needle. C. The eight-plate is slipped over the needle to center this on the physis. D,E. Two 1.6-mm guide pins are inserted parallel to the physis, followed by the self-tapping, cannulated, fully threaded 4.5-mm screws. F. The guide pins are removed and the screws countersunk into the plate. Shown here are 24-mm screws; the alternative is to use the 16-mm screws.

SUPRAMALLEOLAR OSTEOTOMY (SKELETAL MATURITY)

- An incision is made over the medial metaphyseal flare of the tibia.
- Kirschner wires are inserted to guide the saw or osteotome, and the surgeon triangulates for the closing wedge.
- The tibia is cut, leaving lateral cortex intact if possible.
- The fibula is left intact unless the surgeon intends to correct more than 20 degrees of rotation.
- The tibial wedge is removed.
- Smooth, crossed Steinmann pins or plate fixation is used to stabilize tension band vs. intact fibula.
- A below-knee cast is applied and the patient is kept non-weight bearing for 4 weeks.
PEARLS AND PITFALLS

The surgeon should avoid countersinking a transphyseal screw. ■ Fluoroscopy and overdrilling may be necessary for removal.
A vertical transphyseal screw trajectory is optimal.
The surgeon should avoid partially threaded screws. ■ These are easy to strip and are difficult or impossible to remove.
The surgeon should avoid periosteal damage.

POSTOPERATIVE CARE

- Hemiepiphysiodesis
  - No immobilization is required.
  - Immediate weight bearing is permitted.
  - There are no activity restrictions.
  - Follow-up is at 6-month intervals with weight-bearing AP radiographs of the ankles.
  - The implant is removed when the plafond is horizontal, regardless of fibular length.
- Supramalleolar osteotomy
  - The patient uses a cast and crutches for 1 month.
  - The patient can use a 3D boot for the second month.
  - Implants are removed after healing.

OUTCOMES

- Initially there is no visible difference, and the family needs to be aware of this.
- The correction is slow and subtle, so routine follow-up (every 6 months) is imperative.
- Correction to neutral, or slight varus, will take 12 to 24 months on average.
- The implant is removed on correction of the valgus deformity.
- Follow-up should continue until maturity to watch for recurrence deformity.
- Premature physeal closure is exceedingly unlikely.

COMPLICATIONS

- Complications are predominately related to the transphyseal screws, which are rigid, transgressing the physis and pitted against the dynamic forces of growth (Fig 5).

FIG 5 • A. On the left, the physis blew past the retained screw. B. As a result of stripping, this screw spun in place, migrated proximally, and could not be removed. C. As the valgus deformity corrected, this screw head ended up within the ankle, notching the talus (with pain) and proved challenging to retrieve. D. This patient failed to return before overcorrecting into varus. E. The screw could not be removed, necessitating a corrective opening wedge osteotomy (through the screw). F. This 17-year-old boy with Marfan syndrome presented with a bent implant and varus overcorrection. Luckily his hindfoot valgus compensated and no osteotomy was needed. (continued)
Stripping, bending, or breakage of the transphyseal screw may make implant removal difficult or impossible.
If the physis closes in the presence of varus deformity, the only recourse is a corrective osteotomy.
Compared to the transphyseal screw, the medial plates are easier to locate and remove.

REFERENCES
DEFINITION
- Psoas and adductor contractures are most common in cerebral palsy but can occur in any neuromuscular condition owing to disuse, muscular imbalance, or spasticity.
- The degree of contracture varies depending on the patient’s age and the severity of neuromuscular dysfunction.
- Detecting hip flexion contracture (psoas) is challenging.
- The challenge for the adductors is deciding which muscles to lengthen and how much lengthening to do.

ANATOMY
- The psoas is part of the primary hip flexor group, the iliopsoas.
- The psoas muscle originates from the transverse processes of the lumbar vertebrae. The muscle belly passes over the sacrum into the pelvis (FIG 1A).
- At the level of the pelvic brim (superior pubic ramus), the intramuscular tendon can be found.
- At this level, the psoas lies underneath the muscle belly of the iliacus. The femoral neurovascular bundle is superficial to the iliacus (FIG 1B,C).
- The psoas and iliacus tendons combine below the level of the pelvic brim to form a common tendon that inserts on the lesser trochanter.
- The adductor longus, adductor brevis, adductor magnus, and gracilis are clinically considered the adductor group of the hip. Their origins arise from the pubic and ischial rami as well as the pubic tubercle and they insert medially on the femur (adductors) and proximal tibia (gracilis) (FIG 1D).
- The adductor longus has a tendinous origin, the gracilis has a muscular fascia, and the adductor brevis and magnus have muscular origins.
- The anterior branch of the obturator nerve lies in the interval deep to the adductor longus and superficial to the adductor brevis, while the posterior branch of the obturator nerve lies in the interval deep to the adductor brevis and superficial to the adductor magnus.

PATHOGENESIS
- Hip flexion and adduction contractures develop over time due to:
  - Lack of typical functional activities
  - Muscular imbalance between these muscle groups and their antagonists, the hip extensors and abductors, due to either weakness of the antagonists or spasticity of the agonists
  - A hip flexion contracture is typical at birth and persists in infancy up until the time the child begins to stand and walk. In an older child who has not achieved standing and walking ability, a hip flexion contracture therefore may represent a persistence of the normal fetal alignment.
- At birth, the normal amount of hip abduction range of motion is 60 to 90 degrees, significantly greater than the expected range of motion of adults.
- Appropriate musculotendinous length develops during growth as the muscle responds to bone growth and stretch associated with typical childhood activities such as walking, running, and playing. Growth occurs at the musculotendinous junction because of the addition of new sarcomeres.
- Contractures of these structures do not allow the joint to achieve normal positions for daily activities.

NATURAL HISTORY
- Contractures, if severe and persistent, can lead to hip subluxation, hip dysplasia, and ultimately hip dislocation.
- Hip dysplasia and especially hip dislocation are most common with more severe cerebral palsy (quadriplegia, minimally ambulatory or nonambulatory, Gross Motor Function Classification System [GMFCS] IV and V) and in L2- or L3-level myelodysplasia because muscular imbalance at the hip is most severe (innervated hip flexors and adductors, paralyzed abductors and extensors).
- In more functionally mobile children with cerebral palsy (GMFCS I, II, and III), psoas and adductor contractures lead to anterior pelvic tilt, excessive pelvic motion, and lack of hip extension in terminal stance and contribute to crouch.
- Although a scissoring gait is commonly considered to be due to adductor contractures, this visual appearance most commonly results from the combination of hip and knee flexion with internal hip malrotation due to excessive femoral anteversion.
- In longstanding cases, hip dysplasia can lead to degenerative arthrosis.

PATIENT HISTORY AND PHYSICAL FINDINGS
- Physical examination methods include the following:
  - Hip flexion-extension range of motion: Normal walking function requires 7 degrees of extension beyond neutral pelvic position. Therefore, even small contractures limit functional range of motion, shorten step length, and induce compensatory movements.
  - Hip abduction-adduction range of motion: Maximum abduction range of motion during typical walking is only 5 degrees. Therefore, even moderate limitations of hip abduction range of motion may not have functional significance (unless spasticity is also present). Normal hip development may not occur if abduction range of motion is limited.
  - If resistance is felt as the hip is extended and abducted, spasticity is present. Increasingly severe spasticity increases the risk of development of subsequent contracture. For ambulation, spasticity (even in the absence of contracture) can limit movement.
  - Hip flexion and hip abduction strength are tested in the supine position. Lengthening a contracted and weak muscle may adversely affect function. Weak, antagonistic muscle groups (hip extensors, hip abductors) predispose to
FIG 1 • A. Hip flexor anatomy. The psoas arises from the lumbar spine transverse processes. At the level of the pubic ramus, as it exits the pelvis, it has an intramuscular tendon. Note the proximity of the femoral nerve and artery anteriorly. B,C. Transverse plane anatomy of the hip. B. Even though this cross section is slightly distal to the pubic ramus, the reason for recommending an approach underneath (lateral) to the iliacus is clear. C. If the iliacus is retracted anteriorly and medially, the femoral neurovascular structures are protected by the muscle belly of the iliacus. The psoas muscle and tendon can be directly visualized. D. Adductor anatomy. The surgeon can orient himself or herself by identifying the tendinous adductor longus origin. The pectineus is lateral and the gracilis medial. The anterior branch of the obturator nerve lies on the anterior surface of the adductor brevis (deep to the adductor longus) after emerging from the obturator foramen just lateral to the pectineus.
flexion and adduction contractures and contribute to muscle imbalance.
- When examining a child for hip flexion contracture, the examiner should not be misled by the presence of a knee flexion contracture that prevents full extension of the leg. This can be avoided by moving the patient to the side of the examination table and allowing the lower leg to drop off the side of the table.
- Femoral anteverision must also be examined for and ruled out (see Chap. PE-27).
- Accurately identifying and controlling pelvic position is crucial for evaluating hip extension and abduction range of motion.
- For the nonambulatory patient, the examiner should look for hyperlordosis and a flexed, adducted, internally rotated hip. For the ambulatory patient, observation of gait may show hyperlordosis, limited step length, scissoring gait, or crouch gait.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**
- Supine anteroposterior (AP) pelvis radiograph (**FIG 2**)
  - Pelvic obliquity
  - Adducted hip
  - Lordotic pelvis
  - Varying degrees of hip dysplasia
- Gait analysis may reveal:
  - Pelvic obliquity with affected side elevated
  - Limited hip abduction range of motion in late stance and during swing phase
  - Excessive anterior pelvic tilt with or without excessive pelvic range of motion
  - Limited hip extension range of motion in terminal stance

**DIFFERENTIAL DIAGNOSIS**
- Hip dysplasia or dislocation
- Knee flexion deformity
- Hip abductor or extensor weakness
- Excessive femoral anteverision
- Contracture of secondary hip flexors (eg, myelodysplasia)

**NONOPERATIVE MANAGEMENT**
- Physical therapy for range of motion and strengthening
- Positioning aids:
  - Standers
  - Sleeping prone
  - Hip abduction pillow, Scottish Rite brace with thoracolumbar extension
  - Botulinum toxin injections

**SURGICAL MANAGEMENT**

**Preoperative Planning**
- The AP pelvis radiograph is reviewed to rule out hip dysplasia.
- Examination under anesthesia is performed as described above. Under general anesthesia, hypertonicity is no longer present and the true difference between restricted range due to high muscle tone versus musculotendinous contracture can be appreciated.
- Also, the secondary hip flexors (tensor fascia lata and sartorius) can be palpated to rule out secondary contracture (uncommon in cerebral palsy but common in myelodysplasia).

**Positioning**
- The patient is positioned supine.
- The leg is draped free to allow flexion and extension of the hip and knee joints as well as abduction of the hip.
- Care must be taken with draping to ensure access to the anterior pelvis up to the groin crease to allow adequate surgical exposure.

**Approach**
- Various approaches have been described for psoas lengthening.
  - My preferred incision is a 3- to 4-cm oblique incision along the inguinal ligament that starts at the anterior superior iliac spine and is directed inferomedially.\(^3\)
  - Surgeons less comfortable with dissecting the abdominal musculature near the inguinal ligament prefer a more proximal incision at the iliac crest with the abdominal musculature taken off the subcutaneous border of the ilium. The psoas tendon is approached at the same level (the pelvic brim) and therefore the exposure of the tendon is more difficult from this more proximal incision.
  - Sutherland preferred an exposure distal to the inguinal ligament.\(^5\)
- All approaches use the same deep tissue plane underneath (lateral) to the iliacus muscle belly.
- The proximity of the femoral neurovascular structures has been well documented and is a cause for caution.\(^4\)
- The surgical concept of psoas lengthening at the pelvic brim was adapted from Salter’s description of lengthening the psoas tendon while performing a Salter pelvic osteotomy.

**FIG 2** • AP pelvis radiographs. **A.** Common findings of coxa valga (although femoral anteverision cannot be eliminated as a possibility): break in the Shenton line indicating subluxation, incomplete femoral head coverage, pelvic obliquity (right side elevated), mild windswept hips (right adducted), and mild acetabular dysplasia (right greater than left). **B.** In this case, severe hip flexion contractures result in anterior pelvic tilt. The AP pelvis radiograph results in an inlet view (obturator foramina are not visible).
PSOAS LENGTHENING AT THE PELVIC BRIM

Incision and Dissection

- An oblique incision is made along the inguinal ligament starting at the anterior superior iliac spine and extending distal and medial (TECH FIG 1A–C).
- The external oblique fascia is identified and divided just above its attachment on the inguinal ligament (TECH FIG 1D).
- Blunt dissection through the internal oblique and transversus abdominis just medial and adjacent to the anterior superior iliac spine allows access to the inner table of the ilium extraperiosteally (TECH FIG 1E).
- The lateral femoral cutaneous nerve typically crosses the surgical wound and is identified and protected, but sometimes it is medial and not encountered.

Tendon Identification and Division

- With the hip flexed, a finger is passed down along the superior pubic ramus underneath the iliacus and psoas to identify the psoas tendon by palpation (TECH FIG 2A).
- The psoas tendon is visualized by retracting the iliacus medially with an Army-Navy retractor (TECH FIG 2B).
- A right-angled clamp is passed around the psoas tendon (TECH FIG 2C).
- By isolating it from the surrounding muscle, the structure is confirmed to be the psoas tendon.
- Muscle fibers are retracted and the tendon is divided with electrocautery, leaving the muscle intact (TECH FIG 2D).
- Any inflexible (tendinous or myofascial tissues) should be divided. Many patients have a psoas minor tendon, which must also be identified and divided. Muscular tissues are left intact to maintain hip flexor function.
For the adductors, a short transverse (most often) or longitudinal incision over the palpable origin of the adductor longus is used (TECH FIG 3A).

The adductor longus tendon is separated from the surrounding tissues (pectineus laterally, gracilis medially [TECH FIG 3B], and adductor brevis and anterior branch of the obturator nerve deep).

The adductor longus tendon is divided as proximally as possible (TECH FIG 3C,D). For ambulatory patients, this is typically the only tissue that should be lengthened.

If necessary, for nonambulatory patients and for more severe neuromuscular hip dysplasia, a partial or complete division of the adductor brevis and other contracted tissues can be performed.

**TECH FIG 2** • A. With the hip flexed, the interval between the superior pubic ramus and the iliacus is developed with blunt finger dissection to palpate the psoas tendon. B. The psoas tendon is visualized by retracting the iliacus medially with an Army-Navy retractor. C. A right-angled clamp is passed around the psoas tendon. D. The tendon is divided with electrocautery, leaving the muscle intact.

**TECH FIG 3** • Adductor longus tenotomy. A. A short transverse incision (pubis left, knee right) exposes the tendinous origin of the adductor longus (pectineus laterally, gracilis medially). B. A right-angled clamp isolates the adductor longus tendon and muscle. C. As proximally as possible, the origin is divided. D. The preserved anterior branch of the obturator nerve lies on the adductor brevis.
PEARLS AND PITFALLS

| Indications | • In the nonambulatory cerebral palsy patient, hip flexor pathology is fairly routinely recognized and therefore not missed. On the other hand, identification of pathology and indications for psoas lengthening in the ambulatory cerebral palsy patient are less well agreed upon. As a result, I believe that psoas lengthening is too often not included in the surgical plan. |
| Surgical site | • In the 1970s, Bleck recognized that release of the iliopsoas tendon at the lesser trochanter in the ambulatory patient resulted in excessive weakness. Release at that level must be avoided in ambulatory patients. • In nonambulators, the iliopsoas combined tendon can be released from the lesser trochanter, but care must be taken not to violate the apophysis of the lesser trochanter in order to avoid heterotopic bone formation along the iliopsoas tendon sheath postoperatively. |
| Early recurrence | • If significant spasticity is present, pain and spasm may lead to difficulty in maintaining postoperative positioning in extension and abduction, leading to recurrence of hip flexion or adduction contractures. Botulinum toxin injected into the hip flexors and adductors at the time of surgery, effective pain management, and meticulous care to avoid postoperative positioning in flexion and adduction are essential. |
| Obturator neurectomy | • Overcorrection resulting in abduction contracture is a high risk. Because of this iatrogenic risk with limited corrective options, this procedure should be abandoned. Safer, less aggressive procedures are favored. |
| Femoral neurovascular injury | • The femoral nerve, artery, and vein are very close to the psoas tendon but are anterior to the iliacus muscle. The iliacus muscle belly can provide protection for these structures if the surgical approach is deep to it. Other protection is afforded by performing the lengthening of the tendon with the hip in the flexed position to relax the neurovascular structures, directly visualizing the tendon within the muscle belly, and stimulating the tissue with electrocautery first before cutting (if the nerve is nearby, the knee will extend). |
| Inappropriate adductor lengthening | • The combination of femoral anteversion with hip and knee flexion deformity results in the visual appearance of a scissoring gait in ambulatory cerebral palsy patients and is more commonly the cause of scissoring. In ambulators, only adductor longus tenotomy should be performed, and it should be performed rarely. • The adductors are more commonly spastic and contracted in more severe hemiplegic cerebral palsy. Therefore, adductor longus tenotomy is more often necessary. |

POSTOPERATIVE CARE

- Psoas lengthening
  - Postoperative elevation of the leg is avoided because it leads to a flexed hip position.
  - Prone positioning is done two or three times a day for at least 30 minutes.
  - A knee immobilizer promotes not only an extended knee but also an extended hip.
  - After 3 weeks, an active hip flexor strengthening program is instituted.
- Adductor lengthening
  - An abductor pillow is used full time for 3 weeks and part time for the next 3 weeks, and early range of motion is instituted.
  - After 3 weeks, an adductor strengthening program is instituted.
- For both procedures, weight bearing can be instituted as tolerated. These procedures are commonly performed in conjunction with osteotomy surgery, in which case weight bearing is typically begun 3 to 4 weeks postoperatively.

OUTCOMES

- Psoas lengthening is commonly performed in conjunction with femoral osteotomy with or without pelvic osteotomy for treatment of hip dysplasia in nonambulatory patients. A redislocation rate of less than 10% can be expected. In ambulatory cerebral palsy patients, psoas surgery improves dynamic hip dysfunction. There is no evidence that psoas lengthening causes hip flexor weakness.
- Power production (H3 power burst) is maintained.
- When psoas lengthening is performed in conjunction with femoral derotation osteotomy, excessive anterior pelvic tilt may also improve.

COMPLICATIONS

- Excessive hip flexor weakness with tendon release at the lesser trochanter
- Femoral neurovascular injury
- Early recurrence of flexion-adduction deformity
- Worsened anterior pelvic tilt and forward trunk lean when hip flexion deformity is not recognized and treated
- Pelvifemoral instability if scissoring gait is treated with inappropriate adductor surgery

REFERENCES

DEFINITION

- The gait pattern of children with cerebral palsy (CP) is frequently disrupted by dynamic overactivity of the rectus femoris muscle.
- This disruption is characterized by delayed and diminished peak knee flexion in swing phase.
- Surgical transfer of the rectus femoris muscle to the medial hamstrings is usually performed in conjunction with other surgical procedures selected to address all elements of soft tissue and skeletal dysfunction that compromise gait in children with CP.
- This surgical strategy, termed single-event multilevel surgery (SEMLS), requires a comprehensive assessment of gait dysfunction using quantitative gait analysis.
- Proper management (surgical, orthotic, and rehabilitative) in childhood can result in an improved gait pattern that will be sustainable in the adult years.

ANATOMY

- The rectus femoris muscle is a portion of the quadriceps muscle group, which also includes the vastus lateralis, the vastus medialis, and the vastus intermedius muscles.
- The rectus femoris muscle is the only one of the quadriceps muscle group that is considered to be biarticular, as it crosses both the hip joint and knee joint. The remaining three muscles cross only the knee joint.
- The rectus femoris muscle is innervated by the femoral nerve. It has its origin on the anterior inferior iliac spine (direct head) and the innominate portion of the pelvis just proximal to the superior margin of the acetabulum (reflected head) and its insertion on the superior pole of the patella.
- The rectus femoris muscle fuses with the underlying vastus intermedius muscle several centimeters proximal to the superior pole of the patella.
- The rectus femoris muscle and the other three portions of the quadriceps muscle group envelop the patella to form the patellar tendon, which inserts on the tibial tubercle apophysis of the proximal tibia. It serves as a hip flexor and knee extensor.
- The rectus femoris muscle has a relatively small physiologic cross-sectional area and a relatively large ratio of tendon length to muscle fiber length, indicating that it is designed for maximal excursion and diminished force generation.
- In normal gait, the rectus femoris muscle is active in the stance to swing phase transition, where it acts to control the magnitude of the flexion excursion of the knee as the gait velocity increases. It is also active at the end of the swing phase to properly position the knee in the transition from swing to stance phase.
- The remaining three portions of the quadriceps muscle group are active during the loading response of stance phase, where they are essential in providing shock absorption function about the knee as the limb is loaded.

- From a functional perspective, the quadriceps muscle group is actually two groups, the first consisting of the rectus femoris muscle and the second consisting of the three femoris muscles (remaining three muscles).9

PATHOGENESIS

- CP is the consequence of an injury to the immature brain that may occur before, during, or shortly after birth. The nature and location of the injury to the central nervous system (CNS) determines the components of the neuromuscular and cognitive impairments.
- Common functional deficits are related to spasticity, impaired motor control, and disrupted balance and body position senses.
- Although the injury to the CNS is not progressive, the clinical manifestations of CP change over time owing to growth and development of the musculoskeletal system.
- The muscles typically exhibit a purely dynamic dysfunction during the first 6 years of life, characterized by a normal resting length and an exaggerated response to an applied load or stretch.
- With time, between 6 and 10 years of age, the muscles develop a fixed or myostatic shortening, resulting in a permanent contracture.
- As such, it is best to consider CP not as a single specific disease process, but rather a clinical condition with multiple possible etiologies.17

NATURAL HISTORY

- Ambulatory children with CP whose gait is disrupted by overactivity of the rectus femoris muscle typically walk with delayed and diminished knee flexion in swing phase. This may be associated with decreased velocity of hip flexion in the stance to swing phase transition and increased ankle plantarflexion in swing phase, called a “stiff” gait pattern.14,18
- These dynamic gait deviations at the hip, knee, and ankle disrupt the normal limb segment coordination that contributes to functional shortening of the limb during the swing phase of the gait cycle.16 As a result, children with CP who have a stiff gait pattern will exhibit compromised clearance of the limb in swing phase.14,18

PATIENT HISTORY AND PHYSICAL FINDINGS

- The clinical history, as provided by the child and the parents, usually contains complaints of toe dragging, tripping, abnormal shoe wear about the toes, and inability to keep up with peers in play and sports.
- A thorough examination will include the prone rectus femoris test (also known as the Duncan-Ely test).
- A positive slow rectus test indicates fixed shortening of the rectus femoris muscle.
- A positive fast rectus test indicates the presence of spasticity of the rectus femoris muscle.
IMAGING AND OTHER DIAGNOSTIC STUDIES

- Radiographic imaging is not required when determining the need for transfer of the rectus femoris muscle to improve gait in children with CP.
- Relevant data from quantitative gait analysis include temporal parameters, sagittal-plane kinematics at the knee and hip, and dynamic electromyography (EMG) of the rectus femoris muscle.
  - Gait velocity should be greater than 60% of age-matched normal. Children with CP who ambulate with a greatly diminished gait velocity will also exhibit disrupted sagittal-plane knee kinematics in swing phase, which will not be corrected by a rectus femoris muscle transfer.
  - Sagittal-plane knee kinematics will show decreased flexion range and velocity in the stance to swing transition, delayed and diminished peak knee flexion in swing phase, and diminished dynamic range of motion with a rounded or mounded wave form in swing phase (**FIG 1A**).3,10,11
  - Sagittal-plane hip kinematics during the stance to swing phase transition should be evaluated when considering surgical transfer of the rectus femoris muscle (**FIG 1B**).
    - A poor transition at the hip is characterized by decreased flexion range and velocity and is a contraindication to rectus femoris muscle transfer.3
  - Poor hip flexor function in the stance to swing transition will result in delayed and diminished peak knee flexion in swing phase, which will not be corrected by a rectus femoris muscle transfer.

DIFFERENTIAL DIAGNOSIS

- Delayed and diminished peak knee flexion in swing phase may be the consequence of:
  - Inappropriate activity of the rectus femoris muscle in swing phase. Transfer of the rectus femoris muscle is indicated in this situation.
  - Diminished overall gait velocity. This circumstance is a contraindication for transfer of the rectus femoris muscle.
  - Poor hip flexor function in the stance to swing phase transition. This circumstance is a contraindication for transfer of the rectus femoris muscle.
  - Leg-length inequality, when the reference limb is relatively short or the contralateral lower extremity is relatively long. In this situation, there is less need for functional shortening of the reference limb in swing phase. This circumstance is a contraindication for transfer of the rectus femoris muscle.

NONOPERATIVE MANAGEMENT

- In the ambulatory child with CP who is younger than 6 years, neurodevelopmental therapy and gait training may be helpful in improving the stiff gait pattern due to inappropriate activity of the rectus femoris muscle in swing phase.
- In the ambulatory child with CP who is age 6 years or older, there is no effective nonsurgical management of the stiff gait pattern.

**FIG 1** • A. Sagittal plane knee (**A**) and hip (**B**) kinematic plots of a child with a jump gait pattern. The gait cycle appears on the horizontal axis, the direction of motion on the vertical axis. The age-matched normal motion (mean ± 2 SD) appears as a purple band, and the subject’s data are indicated by a blue line. **A.** Kinematic indicators for transfer of the rectus femoris muscle are delayed and diminished peak knee flexion in midswing phase (**circle**), and decreased range and rate of knee flexion in the stance to swing transition (**arrow**). **B.** The kinematic contraindications at the hip for transfer of the rectus femoris muscle at the knee are decreased range and rate of hip flexion in the stance to swing transition (**arrow**). **C.** Dynamic electromyography (EMG) of the rectus femoris muscle in a child with CP. Three gait cycles are shown, separated by the solid black lines. The stance and swing phases of each cycle are separated by the dashed black lines. The normal timing of activation of the muscle is noted by the horizontal red lines at the bottom of the strip. The actual timing of activation of the muscle for the subject is shown by the oscillating red line at the middle of the strip. The dynamic EMG indicator for transfer of the rectus femoris muscle is prolonged and inappropriate activity in midswing phase (indicated by the **circles** in each gait cycle).
SURGICAL MANAGEMENT
- Achieving optimal outcomes after transfer of the rectus femoris muscle requires careful patient selection, proper surgical technique, appropriate postoperative orthotic management, and adequate rehabilitation resources (primarily physical therapy for conditioning and gait training) in the months after the surgery.

Preoperative Planning
- Proper clinical decision making and preoperative planning for surgery to improve gait in children with CP require the integration of data from five fields—clinical history, physical examination, diagnostic imaging, quantitative gait analysis, and examination under anesthesia—in a process described as a diagnostic matrix.

Positioning
- The child is placed on the operating table in the supine position.
- A tourniquet is placed about the most proximal portion of the thigh, and the extremity is carefully cleansed and draped to allow adequate exposure for the surgical approach to the rectus femoris muscle.

Approach
- The rectus femoris muscle is usually exposed via a direct anterior approach at the distal third of the thigh.
- This approach is particularly appropriate when transfer of the rectus femoris muscle and lengthening of the medical hamstring muscles are to be performed at the same time as part of SEMLS.

SOFT TISSUE DISSECTION
- An 8- to 12-cm incision is made over the anterior aspect of the distal third of the thigh, ending one to two fingerbreadths onto the superior pole of the patella (TECH FIG 1).
- The dissection is carried down through the subcutaneous layers to the fascia overlying the quadriceps muscle group.
- This fascial layer is incised for the full length of the incision, exposing the myotendinous portion of the rectus femoris muscle proximally and the superior pole of the patella distally.

ISOLATION OF THE RECTUS TENDON
- The rectus femoris muscle is identified and isolated proximally from the surrounding muscles of the quadriceps muscle group (vastus lateralis muscle laterally, vastus medialis muscle medially, and the vastus intermedius muscle deeply) (TECH FIG 2A).
- The rectus femoris muscle is dissected from proximal to distal, freeing it completely from the surrounding quadriceps muscle group.
- The dissection is carried onto the superior pole of the patella for 1 to 2 cm, and the insertion of the rectus femoris muscle onto the patella is completely released (TECH FIG 2B).
MOBILIZATION OF THE RECTUS FEMORIS TENDON AND TUNNELING

- A transfer stitch is placed into the distal end of the rectus femoris tendon, and the muscle–tendon unit is mobilized from distal to proximal using intermuscular dissection with scissors.
  - The rectus femoris muscle should be completely mobilized proximally to the level between the proximal and middle thirds of the thigh (TECH FIG 3A).
- A subcutaneous tunnel is made between the proximal and medial margin of the incision used to expose the rectus femoris muscle and the distal and anterior margin of the incision used to expose the hamstring muscles (TECH FIG 3B).
  - This tunnel should be superficial to the quadriceps fascia and deep to the majority of the subcutaneous fat of the medial thigh, and expanded to a width of two fingerbreadths.
- The rectus femoris muscle–tendon unit is passed through the subcutaneous tunnel and pulled into the incision overlying the hamstring muscles (TECH FIG 3C).
  - Tension is applied to the rectus femoris tendon using the transfer suture, and the line of pull of the rectus femoris muscle is assessed beneath the proximal margin of the anterior thigh incision.
  - Further proximal release may be necessary to optimize the line of pull of the rectus femoris muscle in its transferred position.

TRANSFER OF THE RECTUS TENDON

- The distal aspect of the rectus femoris tendon is transferred to the distal segment of the semitendinosus muscle tendon, which was previously released in the hamstring muscle lengthening (see Chap. PE-43).
  - The transfer is performed using a single interweaving of the rectus femoris and semitendinosus tendons (modified Pulvertaft technique) (TECH FIG 4).
  - The transfer is tensioned so that the muscle belly of the rectus femoris muscle is slightly tighter to palpation than the muscle bellies of the remaining three muscles of the quadriceps muscle group, when the knee is held in full extension.
- Three separate throws of a nonabsorbable suture are used to secure the transfer.

TECH FIG 3 • Medial views of the right thigh. A. Hip is to the right. Proximal mobilization of the rectus femoris. The rectus femoris muscle is manipulated using the transfer suture (dashed arrow) and released proximally using the scissors (solid arrow). B. Patella is to the left. Orientation of the transfer tunnel between the medial and anterior skin incisions (red arrow). A clamp is placed into the tunnel from distal medial to proximal anterior and used to guide the rectus femoris muscle–tendon unit to its site of transfer insertion (circle). C. The rectus femoris tendon is delivered into the medial incision (solid circle), where it will be transferred to the distal portion of the semitendinosus muscle tendon (dashed circle).

TECH FIG 4 • Medial view of the right thigh (patella is to the left), showing the transfer of the rectus femoris tendon to the semitendinosus muscle tendon using a single interweaving (modified Pulvertaft technique; circle) that will be stabilized by three throws of a nonabsorbable suture.
Distal transfer of the rectus femoris muscle to the medial hamstring muscles should be considered only for children with delayed and diminished peak knee flexion in swing phase due to overactivity of the rectus femoris muscle. When gait velocity is diminished beyond 70% of normal, poor hip flexor function in the stance to swing transition is present, or there is an anatomic or functional leg-length inequality (reference limb short), delayed and diminished peak knee flexion in swing phase will not be improved by transfer of the rectus femoris muscle.

When there is spasticity of the rectus femoris muscle, and the proper kinematic and dynamic EMG indicators are present, failure to perform a rectus femoris transfer at the time of medial hamstring muscle lengthening will result in the development of a stiff gait pattern.²,20

Transfer of the rectus femoris muscle to the sartorius, gracilis, semimembranosus, or semitendinosus muscles will have a comparable benefit on sagittal-plane knee kinematics in swing phase.¹,7,10,11 Of the medial hamstring muscles, the semitendinosus muscle is preferred because of its myoarchitecture (long tendon length) and insertion site on the proximal tibia, which is the furthest from the knee joint center (optimizing the lever arm available for the transferred muscle).⁴

The long anterior thigh incision and intermuscular proximal release of the rectus femoris muscle is a biarticular muscle and should be transferred to another biarticular muscle (such as the semitendinosus).

The line of pull of the transferred muscle–tendon unit should be as straight as possible. The long anterior thigh incision and intermuscular proximal release of the rectus femoris muscle must be performed. Adequate release of the rectus femoris muscle cannot be achieved through a small incision.

The transfer path should occur through a plane that minimizes scarring. The transfer tunnel for the rectus femoris muscle should be at the level of the subcutaneous fat, superficial to the quadriceps fascia.

The muscle transfer should be tensioned so the muscle belly is at a slight stretch, to optimize the length–tension relationship of the transferred muscle. The rectus femoris muscle transfer should be tensioned so the muscle is slightly tighter than the other portions of the quadriceps muscle group.

POSTOPERATIVE CARE

- Transfer of the rectus femoris muscle is rarely performed in isolation for children with CP, but rather a component of SEMLS.
- If complete knee extension has been achieved after lengthening of the medial hamstring muscles and transfer of the rectus femoris muscle, then the knee is protected in a knee immobilizer after surgery. The knee immobilizer is worn full time and the child is kept non-weight bearing for 2 weeks.
- Passive knee range of motion is initiated at 1 to 2 weeks after surgery.
- Weight bearing and gait training are begun 2 to 6 weeks after surgery, depending on which other surgeries have been performed as a part of SEMLS.

Proper rehabilitation under the guidance of an experienced physical therapist is essential, as many children with CP who have undergone simultaneous lengthening of the medial hamstring muscles and distal transfer of the rectus femoris muscle as part of SEMLS will begin to ambulate with a quadriceps avoidance gait pattern. This should be corrected by appropriate gait training early in the rehabilitation phase.

OUTCOMES

- The goals of surgical transfer of the rectus femoris muscle are to improve the timing and magnitude of peak knee flexion in swing phase in order to correct an existing stiff gait pattern or to avoid the development of such a pattern after inappropriate isolated lengthening of the medial hamstring muscles. Improved dynamic alignment at the knee during the swing phase of the gait cycle should result in improved gait efficiency and clearance of the swing limb.
- Improvements in swing-phase knee kinematics after rectus femoris muscle transfer have been documented at 1 year after surgery and have been shown to be maintained at 5 and 10 years of follow-up.¹,5,7,8,10,11,13,15,19,21
- Distal transfer of the rectus femoris muscle to the medial hamstring muscles has been shown to be superior to proximal or distal release alone.¹,10,11,19
- The site of transfer has been shown to have no impact on the dynamic transverse-plane alignment of the hip or knee during stance phase.¹⁰
COMPLICATIONS

■ Theoretical complications, such as suprapatellar rupture of the knee extensor mechanism, lack of knee extension in stance phase due to excessive tightness of the transferred rectus femoris muscle, and weakening of the quadriceps muscle group after transfer of the rectus femoris muscle, have not been reported in the literature.

■ The principal functional complication after transfer of the rectus femoris muscle is persistent quadriceps avoidance gait pattern, which may occur in children with CP who have significant spasticity and anxiety.

■ Proper rehabilitation under the direction of an experienced physical therapist is effective in managing this problem.

■ The principal cosmetic complication after transfer of the rectus femoris muscle is an unsightly scar that may develop at the incision site on the anterior aspect of the thigh. This is a consequence of the preferred incision crossing the skin lines of Langer.

■ Scar formation is minimized by proper incision wound management (pressure applied by massage) during the postoperative rehabilitation phase.

REFERENCES

DEFINITION
- Proximal hamstring lengthenings are primarily performed in the treatment of spastic hip subluxation, mainly in children prior to adolescence.
- Based on modeling studies, the hamstrings are a significant contribution to increasing the force in spastic hip disease, which causes hip subluxation. They are also a component that keeps the knees flexed and secondarily encourages flexion combined with spastic hip flexors, which causes the knee to fall into internal rotation and adduction, magnifying the influence of the concomitant spastic adductors.
- This posture of hip flexion and internal rotation and adduction, with the addition of high muscle force, tends to drive the hip posterosuperiorly out of the acetabulum.
- The primary period during which spastic hip disease occurs is 2 to 8 years of age, although some children are still at risk through their adolescent growth spurt and need to be monitored.

ANATOMY
- Hamstring attachments on the pelvis are very broad muscular attachments and do not have a substantial amount of tendon.
- The exception to this is that the semimembranosus tends to have a tendinous insertion and may be confused with the sciatic nerve if care is not taken.
- There tends to be some broad fascial insertion with both the biceps and the semitendinosus.

PATHOGENESIS
- Spastic hip disease is a pathologic force that has both an abnormal direction of the vector and a force vector that is too high caused by spastic muscles.
- The muscles, in order of their importance, are the adductor longus, the gracilis, the proximal insertion of the hamstrings, and the iliopsoas.
- An important cause of spastic hip subluxation is positioning of the hip into internal rotation and hip flexion and adduction for a significant component of the child’s daily posturing.

NATURAL HISTORY
- Abnormal hip subluxation typically begins around 2 years of age and then has a progression of about 10% of migration every 6 months if the progression is occurring.
- Therefore, physical examination, monitoring of the hip in abduction, and an anteroposterior (AP) pelvis radiograph in which the Reimer migration index is measured every 6 months would be sufficient to pick up early spastic hip disease.

PATIENT HISTORY AND PHYSICAL FINDINGS
- The concern for spastic hip disease is primarily present in children with spasticity, although some adolescents will be at risk.
- The primary physical examination finding is the limitation of hip abduction with hips extended and knees extended.
- Also, a child whose predominant posture both in sitting and lying is with hip flexion adduction and internal rotation is at high risk.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- The primary radiographic investigation is a supine AP pelvic radiograph in which the Reimer migration index is measured.
  - Normal should be 25% or less at all ages. Abnormal is greater than 30%.
  - If there is a question as to whether this is the standard hip subluxation predominantly occurring in the posterosuperior aspect of the acetabulum, a CT scan may be obtained to fully evaluate the position of the hip joint. However, this is not routinely required.

DIFFERENTIAL DIAGNOSIS
- Hip subluxation secondary to developmental hip dysplasia
- Congenital hip dislocation
- Hypotonic hip dislocation

NONOPERATIVE MANAGEMENT
- No conservative treatment options have been documented to be efficacious.
- There have been several attempts at treating spastic hip subluxation with botulinum toxin injection; however, preliminary evidence suggests that the failure rate is high and the need for later reconstruction will be higher than with adequate surgical release.

SURGICAL MANAGEMENT
Preoperative Planning
- The indications for the procedure are a migration index of 30% to 60% in a child who is less than 8 to 10 years of age and has limited hip abduction, meaning less than 30 degrees of hip abduction with hips and knees extended.
- This examination should be performed under anesthesia.
- The goal of the treatment is to have the child lie without any force or pushing with bilateral hip abduction of more than 45 degrees at the end of the operative procedure.
- The indication for proximal hamstring lengthening is a popliteal angle of greater then 45 degrees with the child under anesthesia.

Positioning
- Proximal hamstring release combined with adductor lengthening is performed with the patient supine and with an adhesive drape placed over the groin.
Approach

- There are two approaches to proximal hamstring release.
- One is a straight posterior approach. However, this approach has the negative consequences of going through the area of major weight bearing for sitting.
- For this reason, it is preferred to do an approach through the medial groin as part of an adductor lengthening going through the fascial compartment of the gracilis.
- Only the approach to the gracilis as part of a full adductor lengthening is described here.

EXPOSURE

- An incision is made from the anterior border of the adductor longus for 2 cm posterior in a transverse plane (TECH FIG 1A).
- The adductor longus is identified with a longitudinal opening of the fascia realigning the adductor longus and is completely transected, with vigilance to ensure that the anterior branch of the obturator nerve is protected by visualizing it (TECH FIG 1B).

MYOTOMY

- The gracilis fascia is opened and a complete gracilis myotomy is performed (TECH FIG 2A).
- If the hip abduction with hip extended and under minimal force is now less than 45 degrees, the anterior branch of the obturator nerve is protected and the adductor brevis is identified, and sequential myotomy is performed until more than 45 degrees of abduction is obtained.
- If the child is not and will not be ambulatory and the hip migration is over 50%, the anterior branch of the obturator nerve is transected (TECH FIG 2B).
ILIOPSOAS TENOTOMY

- The interval between the adductor brevis and pectineus or the interval between the pectineus and the neurovascular bundle is opened to the iliopsoas tendon.
- A complete tenotomy of the iliopsoas tendon is performed if the child is nonambulatory. If the child is ambulatory, the tendon is retracted proximally until only the fascia of the psoas is tenotomized, leaving intact the large muscular iliacus (TECH FIG 3).

![TECH FIG 3](image)

HAMSTRING LENGTHENING

- The fascial compartment of the gracilis is opened posteriorly, and, with digital dissection, the posterior compartment muscles of the hamstrings are separated (TECH FIG 4A).
- The interval between the adductor magnus, which does not contract with knee flexion–extension, is separated from the semimembranosus and semitendinosus (TECH FIG 4B).
- The femur is palpated with the finger, and then the semimembranosus and semitendinosus and biceps muscles are all separated, leaving the sciatic nerve against the femur (TECH FIG 4C).
- The sciatic nerve can be palpated on the posterior aspect of the femur along the linea aspera.
- A right-angled clamp is then placed around the muscle mass and it is pulled anteriorly into the surgical wound for visualization with the hip extended and the knees flexed (TECH FIG 4D).
- Electrocautery is used and the muscle is transected.
- Any fascial or tendinous material is carefully inspected and stimulated with a nerve stimulator to make absolutely sure that it is not the sciatic nerve.
- It must be clear that the anesthesiologist has not had the child under paralysis, and there should be good muscle twitches documented by the anesthesiologist.

![TECH FIG 4](image)
COMPLETION AND WOUND CLOSURE

- The popliteal angle is checked again.
- It should have gone from greater than 45 degrees to about 20 to 30 degrees.
- The surgeon should not stretch the popliteal angle without palpating the sciatic nerve, which tends to become very tight, and must be careful not to overstretch the hamstrings at this point for fear of causing sciatic nerve palsy.
- The wounds are closed with a longitudinal closure of the fascial wound and a transverse closure of the subcutaneous wound and skin wound.

POSTOPERATIVE CARE

- The patient is placed in knee immobilizers.
- Pain is controlled typically with morphine and spasticity with diazepam given orally or rectally. Diazepam should be used on a standing order for 48 hours.
- Care is taken not to overstretch the hamstrings, especially in the first 2 or 3 weeks, for fear of causing sciatic nerve palsy, particularly in individuals with severe contractures.
- Removable Velcro enclosed knee immobilizers are used 8 to 12 hours a day.

OUTCOMES

- The goal of the surgical treatment is primarily to improve the child’s standing ability, if the child is able, and secondly to treat the spastic hip disease. About two thirds of patients whose migration index is 30% to 60% and who are 2 to 8 years old will not require further treatment for their spastic hip disease, and the hip subluxation will resolve either completely or to a major level.
- For children whose hip subluxation does not resolve, reconstruction with femoral and pelvic osteotomy may be required.
- It is important to monitor hip radiographs in individuals, even those who have responded well at an early age, throughout their whole adolescent growth, because recurrent subluxation may occur as late as the adolescent growth period.
- After complete maturation of growth, hips should have a migration percentage of less than 40%. There does not need to be further monitoring or concern after the completion of skeletal growth.

COMPLICATIONS

- The primary complication is sciatic nerve palsy. If it occurs, sciatic nerve palsy tends to occur from overstretching the nerve in the postoperative period.
- Wound infections are rare and can usually be treated with local care.
- Heterotopic ossification may occur, especially if the iliopsoas is released through the apophysis of the lesser trochanter.
- Proximal hamstring lengthenings during adolesence also run an increased risk of developing heterotopic ossification in the proximal muscle release site.

REFERENCES

DEFINITION
- The gait pattern of children with cerebral palsy (CP) is frequently disrupted by dynamic overactivity and shortening of the medial hamstring muscles.
- This disruption is characterized by increased knee flexion in stance phase, and decreased knee extension at the end of swing phase.
- Surgical lengthening of the medial hamstrings is usually performed in conjunction with other surgical procedures selected to address all elements of soft tissue and skeletal dysfunction that compromise gait in children with CP.
- This surgical strategy, termed single-event multilevel surgery (SEMLS), requires a comprehensive assessment of gait dysfunction using quantitative gait analysis.
- Proper management (surgical, orthotic, and rehabilitative) in childhood can result in an improved gait pattern that will be sustainable in the adult years.

ANATOMY
- The medial hamstrings consist of three muscles: the gracilis, the semimembranosus, and the semitendinosus. All three are considered biarticular muscles because they cross both the hip joint and knee joint.
  - The gracilis muscle is innervated by the obturator nerve and has its origin on the inferior pubic ramus and its insertion on the anteromedial aspect of the proximal tibia. It serves as a hip adductor and knee flexor. The gracilis muscle has a relatively small physiologic cross-sectional area and a relatively large ratio of tendon length to muscle fiber length, indicating that it is designed for maximal excursion and diminished force generation.7,9
  - The semimembranosus muscle is innervated by the sciatic nerve and has its origin on the inferior pubic ramus and其 insertion on the posteromedial aspect of the proximal tibia. It serves as a hip extensor and knee flexor. The semimembranosus muscle has a relatively large physiologic cross-sectional area and a relatively small ratio of tendon length to muscle fiber length, indicating that it is designed for minimal excursion and increased force generation.7,9
  - The semitendinosus muscle is innervated by the sciatic nerve and has its origin on the inferomedial portion of the ischium and its insertion on the posteromedial aspect of the proximal tibia. It serves as a hip extensor and knee flexor. The semitendinosus muscle has a relatively small physiologic cross-sectional area and a relatively large ratio of tendon length to muscle fiber length, indicating that it is designed for maximal excursion and diminished force generation.7,9
- The lateral hamstrings consist of the biceps femoris muscle, which is innervated by the sciatic nerve. The muscle is considered to be uniarticular, crossing only the knee joint, with its origin on the posterior aspect of the middle third of the femur and its insertion on the fibular head. It serves as a knee flexor.

PATHOGENESIS
- CP is the consequence of an injury to the immature brain that may occur before, during, or shortly after birth. The nature and location of the injury to the central nervous system (CNS) determines the neuromuscular and cognitive impairments.
- Common functional deficits are related to spasticity, impaired motor control, and disrupted balance and body position senses.
- Although the injury to the CNS is not progressive, the clinical manifestations of CP change over time because of growth and development of the musculoskeletal system. The muscles typically exhibit a purely dynamic dysfunction during the first 6 years of life, characterized by a normal resting length and an exaggerated response to an applied load or stretch. With time, between 6 and 10 years of age, the muscles develop a fixed or myostatic shortening, resulting in a permanent contracture.
- As such, it is best to consider CP not as a single specific disease process, but rather a clinical condition with multiple possible causes.14

NATURAL HISTORY
- Ambulatory children with CP whose gait is disrupted by overactivity and shortening of the medial hamstring muscles typically walk with increased knee flexion in stance phase and diminished knee extension in swing phase.
  - This is usually associated with increased ankle plantarflexion in stance phase and is called a “jump” gait pattern.12,16
  - Children with a jump gait pattern will have overactivity of the medial hamstring muscle group; the lateral hamstring muscle group is rarely involved.
  - As the child gets older and heavier, ankle plantarflexor insufficiency (due to muscle weakness and foot segmental malalignment) will eventually occur. This will result in increasing ankle dorsiflexion and knee flexion in stance phase, which is called a “crouch” gait pattern.12,16
  - Teenagers with a severe crouch gait pattern will have involvement of both the medial and lateral hamstring muscle groups.
  - As the ground reaction force falls further and further behind the knee during the stance phase in crouch gait, the demands on the knee extensor muscles increase, eventually resulting in painful patellofemoral overload.
  - For this reason the crouch gait pattern is not sustainable, and by the late teenage or young adult years individuals with this gait pattern frequently lose the ability to ambulate.
PATIENT HISTORY AND PHYSICAL FINDINGS

- The clinical history, as provided by the child and the parents, usually contains complaints of inability to stand up straight, inability to keep up with peers in play and sports, inability to walk distances (such as at the grocery store or the mall), and anterior knee pain after walking activities or at the end of the day.

- A straight-leg raise of 60 degrees or less is indicative of shortening of the medial hamstrings.

- A popliteal angle of 45 degrees or greater is indicative of shortening of the medial hamstrings.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Radiographic imaging is not required when determining the need for lengthening of the medial hamstrings to improve gait in children with CP.

- If lateral radiographs of the knee are obtained, however, they will frequently show patella alta, with fragmentation of the inferior pole of the patella; these are the sequelae of chronic and progressive patellofemoral overload (FIG 1).

- Relevant data from quantitative gait analysis include sagittal-plane kinematics and kinetics at the knee, and dynamic electromyography (EMG) of the medial hamstrings.

  - Sagittal-plane knee kinematics will show increased knee flexion of greater than 20 degrees at initial contact in loading response at the beginning of stance phase, and diminished knee extension at terminal swing at the end of swing phase (FIG 2A).

  - In jump gait pattern, full knee extension in midstance may occur. This is not a contraindication to lengthening of the medial hamstrings.

  - In crouch gait pattern, increased knee flexion will be of greater magnitude and is present throughout the stance phase.

  - Sagittal-plane knee kinetics will show an increased internal knee extension moment in stance phase (FIG 2B).

FIG 1 • Standing lateral radiograph of the knee in a child with cerebral palsy and a crouch gait pattern. There is a patella alta, with fragmentation of the inferior pole of the patella, indicating chronic overload of the knee extensor mechanism.

FIG 2 • Sagittal-plane knee kinematic plots of a child with a jump gait pattern (A) and kinetic plots of a child with crouch gait pattern (B). The age-matched normal motion (mean ± 2 standard deviations) appears as a light purple band and the subject’s data are indicated by a blue line. A. The gait cycle is on the horizontal axis, the direction of motion on the vertical axis. Kinematic indicators for lengthening of the medial hamstrings are increased flexion at initial contact and diminished extension at terminal swing (arrows). B. The gait cycle is on the horizontal axis, the internal moment on the vertical axis. Crouch gait pattern is characterized by an increased internal extension moment at the knee throughout stance phase (red arrows). C. Dynamic electromyography (EMG) of the medial hamstrings in a child with cerebral palsy. Three gait cycles are shown, separated by the solid vertical lines. The stance and swing phases of each cycle are separated by the dashed vertical lines. The normal timing of activation of the muscle is noted by the horizontal red lines at the bottom of the strip. The actual timing of activation of the muscle for the subject is shown by the oscillating red line at the middle of the strip. The dynamic EMG indicator for lengthening of the medial hamstring muscles is prolonged activity in midstance (indicated by the circles in each gait cycle).
In jump gait pattern, the increased knee moment will occur in the loading response and terminal stance subphases of stance phase.

In crouch gait pattern, the increased knee moment will be of greater magnitude and will occur throughout the stance phase.

Dynamic EMG of the medial hamstrings will show prolonged activity of the muscle group into the mid- and terminal stance subphases of stance phase (FIG 2C).

**DIFFERENTIAL DIAGNOSIS**

- Increased knee flexion in stance phase may be the consequence of:
  - Overactivity or shortening of the medial hamstring muscles
  - Surgical lengthening of the medial hamstring muscles is appropriate.
  - Ankle plantarflexor insufficiency, with disruption of the ankle plantarflexion–knee extension couple. This may be a consequence of muscle weakness or foot skeletal segmental malalignment, resulting in lever arm deficiency.6,8,15
  - The ankle plantarflexor insufficiency must be addressed directly to improve the gait deviation at the knee.
  - Dyskinetic CP, with disrupted balance and body position sense. In such cases, mildly increased knee flexion in stance phase gives a sense of stability to the child and is habitual.
  - Surgical lengthening of the medial hamstring muscles will not correct the gait deviation in this situation.
  - Increased knee flexion at the end of swing phase may be a consequence of:
    - Overactivity or shortening of the medial hamstring muscles
    - Surgical lengthening of the medial hamstring muscles is appropriate.
    - Increased ankle plantarflexion at the end of swing phase. Increased knee flexion will occur in swing phase to promote limb clearance and improve the foot position in the transition from swing to stance phase.
  - Decreased hip flexion in swing phase. Increased knee flexion will occur in swing phase to promote limb clearance.

**NONOPERATIVE MANAGEMENT**

- In children less than 6 years of age, with primarily dynamic deformity of the medial hamstrings, a community- or home-based stretching program may be effective at improving knee extension during gait for a limited period of time.
- Injection of botulinum toxin into the medial hamstrings, which decreases muscle spasticity via a reversible neuromuscular blockade, may also be effective for dynamic deformity in younger children.3
- Serial stretch casting of the knee has been shown to be effective for the treatment of mild myostatic deformity of the medial hamstrings, particularly after surgical lengthening.18
- Use of an ankle–foot orthosis may be effective treatment for increased knee flexion in stance phase that is the consequence of ankle plantarflexor insufficiency and disruption of the ankle plantarflexion–knee extension couple.5

**SURGICAL MANAGEMENT**

- Achieving optimal outcome after lengthening of the medial hamstring muscles requires careful patient selection, proper surgical technique, appropriate postoperative orthotic management, and adequate rehabilitation resources (primarily physical therapy for conditioning and gait training) in the months after the surgery.

**Preoperative Planning**

- Optimal clinical decision making and preoperative planning require the integration of data from five fields—clinical history, physical examination, diagnostic imaging, quantitative gait analysis, and examination under anesthesia—in a process described as a diagnostic matrix.4
- When considering lengthening of the medial hamstrings, the examination under anesthesia should include repeating the straight-leg raise and popliteal angle measurements as described above.
  - In children with CP that includes significant spasticity, it is frequently difficult to determine the relative contributions of dynamic overactivity and myostatic contracture to muscle deformity and dysfunction. When the child is under anesthesia, the spastic component is effectively removed, allowing the physician to perform a clinical examination to determine the presence or absence of myostatic or fixed muscle shortening.
  - Surgical lengthening of the muscle is most appropriate when significant myostatic or fixed shortening is present.
  - Lengthening of the lateral hamstring muscle is not necessary for children with either jump or crouch gait patterns.
  - Lateral hamstring lengthening is indicated only for teenagers with a severe crouch gait pattern, whose popliteal angle measurement fails to improve adequately (as described below) after lengthening of the medial hamstring muscles.

**Positioning**

- The child is placed on the operating table in the supine position.
- A tourniquet may be placed about the most proximal portion of the thigh. The extremity is carefully cleaned and draped to allow adequate exposure for the surgical approach to the medial hamstring muscles. Use of a tourniquet to minimize blood loss and maximize the operative exposure is favored when performing SEMLS that includes both soft tissue and skeletal surgeries.

**Approach**

- The medial hamstring muscles are usually exposed via a posteromedial approach at the distal third of the thigh.
- This approach is particularly appropriate when lengthening of the medial hamstring muscles and transfer of the rectus femoris muscle are to be performed at the same time as part of SEMLS.
LENGTHENING OF THE MEDIAL HAMSTRING MUSCLES (IN CONJUNCTION WITH TRANSFER OF THE RECTUS FEMORIS MUSCLE)

- A 6- to 10-cm incision is made over the posteromedial margin of the distal third of the thigh, ending two or three fingerbreadths proximal to the posterior skin crease of the knee joint (TECH FIG 1A).
- The incision is carried down through the subcutaneous tissues, past the saphenous vein and the sartorius muscle, exposing the three muscles of the medial hamstring muscle group (TECH FIG 1B).
  - The gracilis and semimembranosus muscles are exposed at the level of their myotendinous junction, and the semitendinosus is exposed at the level of its distal tendon.
- A proximal tenodesis is performed between the gracilis (at its myotendinous junction) and the semitendinosus (at its proximal tendon), using two throws of a nonabsorbable suture (TECH FIG 1C).
  - The semitendinosus muscle is then completely transected 1 cm distal to the tenodesis with the gracilis muscle (TECH FIG 1D).
- A fractional lengthening of the semimembranosus muscle is performed, using two transverse incisions, separated by 2 cm, through the broad and thin tendon overlying the muscle at the musculotendinous junction (TECH FIG 1E).
  - Care should be taken not to cut the muscle tissue underlying the tendon at this level.
- A fractional lengthening of the gracilis muscle is performed, using a single transverse incision located 1 cm distal to the tenodesis with the semitendinosus (TECH FIG 1F).
  - Care should be taken not to cut the muscle tissue underlying the tendon at this level.
- Repeat assessment of the popliteal angle is made after lengthening of the medial hamstring muscles.
  - The angle should be improved (ie, decreased) by 30 to 40 degrees.

**TECH FIG 1** • Medial views of the right knee. A. The posteromedial skin incision used for exposure of the medial hamstring muscles. B. The three muscles of the medial hamstrings group—the gracilis (solid arrow), the semimembranosus (dashed arrow), and the semitendinosus (dotted arrow). Each has distinct myoarchitecture. C. Proximal tenodesis of the gracilis and the semitendinosus muscles (circle). D. The tendon of the semitendinosus has been transected (arrow) distal to the tenodesis (red circle). E. A two-level fractional lengthening (arrows) of the semimembranosus muscle has been performed. F. A fractional lengthening (arrow) of the gracilis muscle has been performed distal to the tenodesis of the gracilis and semitendinosus muscles (circle).
LENGTHENING OF THE LATERAL HAMSTRING MUSCLE

- A 3- to 5-cm incision is made over the posterolateral margin of the distal third of the thigh, posterior to the posterior margin of the iliotibial band, ending three to five fingerbreadths proximal to the head of the fibula (TECH FIG 2A).
- The incision is carried down through the subcutaneous tissues, past the posterior margin of the iliotibial band, exposing the biceps femoris at the level of its myotendinous junction (TECH FIG 2B).

The common peroneal nerve, which is located adjacent to the posteromedial margin of the biceps femoris muscle, should be identified and gently retracted away from the muscle before lengthening.
- A fractional lengthening of the biceps femoris muscle is performed, using a single transverse incision (TECH FIG 2C).
- Care should be taken not to cut the muscle tissue underlying the tendon at this level.

FRACTIONAL LENGTHENING OF THE MEDIAL HAMSTRING MUSCLES (WITHOUT CONCOMITANT TRANSFER OF THE RECTUS FEMORIS MUSCLE)

- A 6- to 10-mm incision is made over the posteromedial margin of the thigh, at the juncture between the middle and proximal thirds (TECH FIG 3A).
- The incision is carried down through the subcutaneous tissues, exposing the three muscles of the medial hamstring group.

The gracilis, semimembranosus, and semitendinosus muscles are all exposed at the level of their myotendinous junction (TECH FIG 3B).
- A fractional lengthening of each of the three muscles is performed, using two transverse incisions, separated by 2 cm, for the semimembranosus muscle, and a single...
incision each for the gracilis and semitendinosus muscles, through the broad and thin tendon overlying the muscle at the musculotendinous junction.

- Care should be taken not to cut the muscle tissue underlying the tendon at this level (TECH FIG 3C).

- Repeat assessment of the popliteal angle is made after fractional lengthening of the medial hamstring muscles. The angle should be improved (ie, decreased) by 15 to 30 degrees.

### COMBINED FRACTIONAL LENGTHENING AND TRANSFER OF MEDIAL HAMSTRING MUSCLES (WITHOUT CONCOMITANT TRANSFER OF THE RECTUS FEMORIS MUSCLE)

- A 6- to 10-cm incision is made over the posteromedial margin of the distal third of the thigh, ending two to three fingerbreadths proximal to the posterior skin crease of the knee joint (TECH FIG 4A).

- The incision is carried down through the subcutaneous tissues, past the saphenous vein and the sartorius muscle, exposing the three muscles of the medial hamstrings group.

  - The gracilis and semimembranosus muscles are exposed at the level of their myotendinous junction, and the semitendinosus is exposed at the level of its distal tendon.

  - A clamp is placed on the proximal portion of the tendon of the semitendinosus muscle, and the tendon is transected distally (TECH FIG 4B).

- The gracilis muscle is transected proximally at the myotendinous junction, and the proximal portion of the muscle is released (TECH FIG 4C).

- The gracilis and semitendinosus muscles are retracted to expose the myotendinous junction of the semimembranosus muscle, where a two-level fractional lengthening is performed (TECH FIG 4D).

- The proximal portion of the semitendinosus muscle–tendon unit is transferred to the distal portion of the gracilis tendon and is secured with two throws of a nonabsorbable suture (TECH FIG 4E).

- Repeat assessment of the popliteal angle is made after combined fractional lengthening and transfer of the medial hamstring muscles. The angle should be improved (ie, decreased) by 30 to 40 degrees.

TECH FIG 4 • Medial view of the right knee.

- A. The posteromedial skin incision used for exposure of the medial hamstring muscles. 
- B. A clamp is placed on the proximal portion of the tendon of the semitendinosus muscle (solid circle), and the tendon (dotted line) is released distally (dotted circle). 
- C. The tendon of the gracilis muscle (arrow) is released proximally at the muscle’s myotendinous junction (circle). 
- D. A two-level fractional lengthening (arrows) of the semimembranosus muscle has been performed. 
- E. The proximal portion of the semitendinosus muscle–tendon unit (dotted arrow) is transferred to the distal portion of the tendon of the gracilis muscle (solid arrow). The transfer is secured with two throws of a nonabsorbable suture (circle).
In older children and teenagers with a longstanding jump or crouch gait pattern, lengthening of the popliteal angle should improve by 30 to 40 degrees on the examination after lengthening of the medial hamstring muscles. Aggressive lengthening to “improve” the popliteal angle closer to 0 degrees may result in excessive lengthening, and subsequent weakness, of the medial hamstring muscles. It is the change in, not the absolute magnitude of, the popliteal angle that is the proper goal of the surgical lengthening.

**Hamstring lengthening should be considered only for children with increased knee flexion in stance phase due to overactivity or fixed shortening (ie, contracture) of the hamstring muscles. Increased knee flexion due to ankle plantarflexor insufficiency (best managed by appropriate soft tissue and skeletal surgery at the foot and ankle, and appropriate orthotic management) will not be improved by lengthening of the hamstrings.**

**POSTOPERATIVE CARE**

- Lengthening of the hamstring muscles is rarely performed in isolation for children with CP; rather, it is usually a component of SEMLS.
- If full knee extension against gravity can be achieved immediately after surgery, use of a knee immobilizer is appropriate. Passive knee range of motion is initiated at 1 to 2 weeks after surgery.
- Weight bearing and gait training are begun 2 to 6 weeks after surgery, depending on which other surgeries have been performed as a part of SEMLS.
- If full knee extension cannot be achieved, a long-leg fiberglass cast is applied with the knee positioned in extension against gravity alone.
- The cast is univalved in the operating room to accommodate postoperative swelling and facilitate spreading of the cast in the first few days after surgery.
- Gradual serial stretch casting, correcting the residual knee flexion deformity at a rate of 5 degrees per week, is instituted.
- **Intermediate follow-up at 10 years after SEMLS has shown that kinematic and kinetic improvements after surgery are maintained despite deterioration in the static findings on physical examination.**

**COMPLICATIONS**

- The most common and significant early complication after lengthening of the hamstrings is neuropraxia of the sciatic nerve, which is due to excessive stretching of the nerve after correction of the dynamic and static knee flexion deformities.
- Neuropraxia of the sciatic nerve is characterized by pain and hypersensitivity about the foot. When this problem is encountered acutely in the immediate postoperative period, the position of immobilization of the knee should be adjusted toward increased flexion to relax the nerve.
- If a neuropraxia develops during the period of serial stretch casting of a residual knee flexion contracture, the stretch casting should be terminated for 1 to 2 weeks, and then resumed at a slow rate.
- If a neuropraxia is first appreciated during the rehabilitation period, management with medications such as gabapentin (mechanism of effect unknown) and physical therapy modalities for desensitization are appropriate.
- Recurrence of knee flexion deformity and increased knee flexion during the stance phase of gait may occur in the years after surgery due to a variety of factors.
As children grow, they pass through finite periods of accelerated rates of growth (growth spurts), where the longitudinal growth of the bones is greater than that of the muscles.

- Muscle shortening may recur and is usually effectively treated with a period of home- or community-based stretching exercises.

- As children grow, they get heavier, and as a result greater muscle forces are required to balance external forces during gait. Weakness of the ankle plantarflexor, knee extensor, and hip extensor muscles is common and may result in development of a crouch gait pattern in the years after SEMLS.

- Avoidance of obesity and ongoing muscle strength training and cardiovascular conditioning are important elements for maintaining optimal gait function in children with CP.

REFERENCES

DEFINITION
- Lengthening of the gastrocnemius fascia is commonly performed for conditions in which the patient positions the foot in equinus while either standing or walking.
- Equinus is defined as plantarflexion of the ankle. It can be measured both clinically and radiographically.
- The most common condition in which this procedure is performed is cerebral palsy, but other disorders, such as idiopathic toe walking, posttraumatic or surgical treatments, and other neuromuscular disorders, such as Duchenne muscular dystrophy, can also result in an equinus of the foot.
- Patients with some disorders, such as Charcot-Marie-Tooth disease, may appear to have equinus, but the true deformity is plantarflexion of the midfoot.

ANATOMY
- The medial and lateral heads of the gastrocnemius muscles, the soleus and the plantaris muscles, form the triceps surae. Although all are part of the same muscle group, their structure and function differ.
- The larger medial head of the gastrocnemius arises from the popliteal surface of the femur just above the medial femoral condyle, and the lateral head originates from the superolateral surface of the lateral femoral condyle.
- The medial and lateral muscle bellies insert into a midline tendinous raphe that widens into the aponeurosis of the gastrocnemius at or just above the midcalf. This tendon unites with the soleus and forms the conjoined tendon, which inserts into the calcaneus by way of the tendo Achilles.
- The gastrocnemius spans the ankle and knee joint and therefore can plantarflex the ankle or flex the knee.
  - It typically has fast twitch type II muscle fibers, which are responsible for short, powerful bursts of activity, such as running and jumping.
- The soleus lies deep (anterior) to the gastrocnemius muscle. It originates on the proximal tibia and inserts with the gastrocnemius into the conjoined tendon. Contraction results in only ankle plantarflexion. It is made up of primarily slow twitch type I muscle fibers and is responsible for primarily postural control.
- The plantaris arises just above the lateral head of the gastrocnemius and inserts into the calcaneus. It is largely vestigial and should be released at the time of surgery.
- The gastrocnemius can be selectively released or lengthened either at its origin, which is uncommonly done, or the tendon of the gastrocnemius, proximal to the conjoined tendon.
  - Lengthening at or below the conjoined tendon (ie, the tendo Achilles) lengthens the entire triceps surae.

PATHOGENESIS
- Equinus positioning of the foot can occur due to:
  - Increased tone or spasticity of the triceps surae muscles
  - Shortening of some or all of the muscles
  - Joint contracture
  - Bony deformity
- It is critical to determine the cause of the equinus because the treatment options differ in each circumstance.
- The initiating cause of this disorder varies.
  - Spasticity, weakness, and subsequent shortening of the muscle group can occur secondary to neuromuscular disorders such as cerebral palsy.
  - Relative shortening of the triceps surae, as occurs when the tibia is lengthened, or fixed positioning of the foot in equinus, such as prolonged casting in plantarflexion, can result in equinus of the ankle.
  - Bony changes at the ankle due to trauma or congenital disorders may also result in equinus.

NATURAL HISTORY
- The natural history varies according to each disease process and the prior treatment history.
- In patients with cerebral palsy, equinus tends to worsen if untreated. It may progress from increased tone to muscle tightness, joint contracture, and eventually bony deformity if untreated.
- Other disorders, such as idiopathic toe walking, often improve as the patient matures into adulthood.

PATIENT HISTORY AND PHYSICAL FINDINGS
- Range of motion of the ankle should be assessed with the ankle in a neutral position.
  - Hindfoot valgus will allow for false (pseudo) dorsiflexion.
- The examination should be performed with the knee extended to assess gastrocnemius tightness and flexed to assess the soleus.
  - If the foot remains in equinus with the knee flexed, there is shortening of the soleus or joint contracture or bony deformity.
  - If the ankle can be dorsiflexed with the knee flexed, but not extended, then the equinus is due to gastrocnemius tightness only (Silfverskiöld test).
- Observational or instrumented gait analysis is important to integrate the physical findings with functional deficits. The patient should be evaluated walking and running.
  - Small limitations in dorsiflexion range may have little functional deficit.
  - Standing and walking or running foot position may differ greatly.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- Standard standing lateral radiographs of the feet are the best method to assess ankle equinus.
- Bony deformity can also be evaluated from this examination.
The angle between horizontal and a line drawn to the plantar aspect of the os calcis should be 15 degrees (0 and 30 degrees) (FIG 1).

The distal tibial should angle open anteriorly 10 degrees (the angle between a line drawn through the tibia and along the distal surface of the tibia should measure 80 degrees anteriorly, or 78 to 82 degrees). Angle B: the angle between horizontal and a line drawn to the plantar aspect of the os calcis should be 15 degrees (0 and 30 degrees).

DIFFERENTIAL DIAGNOSIS
- Cerebral palsy, Duchenne muscular dystrophy, and other neuromuscular disorders
- Idiopathic toe walking
- Congenital (fibular hemimelia)
- Bony deformity (posttraumatic, malalignment, asymmetric growth arrest)
- Prior immobilization
- Prior tibial lengthening

NONOPERATIVE MANAGEMENT
- Physical therapy and stretching is the most common form of treatment for mild deformities and is used in an attempt to maintain range gained by other methods.
  - The knee must be extended and the hindfoot placed in a neutral position when stretching the ankle.
  - Bracing, nighttime splinting, or both can be used in combination with other techniques. It is primarily used to maintain gains or prevent worsening deformity.
  - Botulinum toxin causes paralysis by blocking acetylcholine release at the neuromuscular junction.
  - It can be injected into the gastrocnemius muscle bellies in an attempt to decrease tone.
  - The effect lasts about 3 months, and therapy or casting can be combined with it.
- Serial casting involves a series of short-leg casts that are placed with the knee flexed and gentle dorsiflexion pressure.
  - They are changed weekly or biweekly, each time with increasingly greater dorsiflexion.
  - Usually three or four casts are used until satisfactory range is obtained.
  - Recurrence is common, and if not carefully performed, skin breakdown can occur.

SURGICAL MANAGEMENT
- The surgical management of equinus varies depending on the cause.
- Lengthening of gastrocnemius fasciae is indicated if:
  - The gastrocnemius is selectively tight
  - This results in functional deficits
  - Conservative (nonoperative) treatment has failed

Preoperative Planning
- Planning should involve assessment of the entire patient, especially in patients with underlying neuromuscular disorders.
- Isolated lengthening of the gastrocnemius fascia in patients with cerebral palsy and tight hamstrings may result in a crouch gait.
- The Silfverskiöld test should be repeated under anesthesia.
- The surgeon should be prepared to do additional procedures if lengthening of the gastrocnemius fascia does not result in sufficient dorsiflexion range.

Positioning
- The patient can be positioned either supine, with the leg externally rotated to gain access to the posterior medial calf, or prone.
- Supine positioning allows other concomitant procedures to be done, but prone positioning allows for easier access.
- We typically perform this procedure with the patient in the supine position, with tourniquet control.

Approach
- The procedure is classically performed through a 2- to 4-inch incision made posteriorly over the midcalf, with the patient prone.
- An incision can be made posteromedially with the patient supine (FIG 2).
STRAYER PROCEDURE

- Dissection is carried down to the facial posterior fascia. This should not be confused with the gastrocnemius tendon (TECH FIG 1A).
- The saphenous vein must be protected medially and the sural nerve laterally (TECH FIG 1B).
- The fascia overlying the (superficial) posterior compartment is divided and the underlying tendon is identified. Often the muscle bellies of the medial and lateral head of the gastrocnemius overlie the tendon and need to be carefully retracted (TECH FIG 1C).
- The tendon of the gastrocnemius is identified proximal to the conjoined tendon and the interval in between the gastrocnemius tendon and the underlying soleus fascia may need to be developed. It can be isolated with an instrument (TECH FIG 1D) and carefully divided, avoiding injury to the underlying soleus fascia and muscle (TECH FIG 1E).
- The ankle should now dorsiflex to 10 degrees with the knee extended (TECH FIG 1F).
- The subcuticular closure is performed in layers, and a cast is placed with the foot in neutral or slight dorsiflexion.

TECHNIQUES
BAKER PROCEDURE

- This technique is identical to the Strayer technique with the exception of the cut through the aponeurosis of the gastrocnemius tendon.
- An inverted-U incision is made through the aponeurosis; the lateral and medial portions remain intact with the underlying soleus muscle (TECH FIG 2A).
- The middle (or tongue) portion is dissected from the soleus, and the distal attachments of the lateral and medial portions of the aponeurosis are freed from the tendon (TECH FIG 2B).
- After lengthening, the four corners of the overlapping portion of the tendon are secured with sutures (TECH FIG 2C).
- The closure and postoperative care are similar to the Strayer procedure.

![TECH FIG 2](image)

The Baker technique.
A. Incision. B. The “box” cut in the gastrocnemius fascia. C. The lengthened tendon, with sutures placed.

VULPIUS PROCEDURE

- This technique is similar to the Baker technique, except that an inverted-V incision is used to divide the aponeurosis of the gastrocnemius tendon (TECH FIG 3A).
- More than one incision can be used if needed (TECH FIG 3B).

![TECH FIG 3](image)

The Vulpius technique.

PEARLS AND PITFALLS

| Indications                      | ■ The patient should be carefully examined to ensure that this is isolated gastrocnemius tightness.  
|                                 | ■ In patients with cerebral palsy, the surgeon should assess and lengthen the hamstrings to avoid a crouch gait.  
| Positioning                     | ■ Patient position depends on the surgeon’s preference and what other procedures may be needed.  
|                                 | ■ Tourniquet control is helpful.  
| Avoid over- or underlengthening | ■ If satisfactory dorsiflexion is not obtained, additional procedures may be needed, including capsular release.  
|                                 | ■ The surgeon should not lengthen beyond 10 to 15 degrees of dorsiflexion.  

POSTOPERATIVE CARE

■ Although Strayer and Baker originally described a “toe-to-groin cast,” typically a short-leg weight-bearing cast is worn for 4 weeks, with knee immobilizers to keep the knees extended when not ambulatory.  
■ Bracing and nighttime splinting can be used to help maintain foot position.

OUTCOMES

■ Significant improvements in range of motion, dynamic joint motion during gait, and electromyographic pattern are typically seen.  
■ Little difference has been shown between the different techniques for lengthening the gastrocnemius fascia.

COMPLICATIONS

■ Lengthening of the gastrocnemius fascia is generally a safe procedure, with few complications.  
■ Overlengthening of the triceps surae is considered to be less likely with this technique than by lengthening more distally at the Achilles tendon. Overlengthening is difficult to treat.  
■ Injury to the sural nerve or saphenous vein is possible but uncommon and carries few long-term deficits.  
■ Recurrence is the most common concern and is probably related more to poor postoperative therapy and splinting than surgical technique.

REFERENCES

DEFINITION
- Crouch gait is defined as walking with excessive knee flexion during stance.
- Crouch is a common walking pattern in neuromuscular conditions, particularly for individuals with cerebral palsy.
- Many potential abnormalities of bone alignment and joint flexibility can accompany or lead to crouch gait.
- Persistent crouch in adolescence frequently results in fixed knee flexion deformity and patella alta.
- Potential contributing factors include hamstring contracture, hip flexion deformity, foot deformity, loss of plantarflexion–knee extension couple, excess femoral anteversion, and external tibial torsion. Weakness and impaired motor control are contributing factors. For some patients, disorders of balance or sensory impairments are major contributors.^{1}
- Fixed knee flexion deformity is oftentimes associated with patella alta. Fixed knee contracture and patella alta are the components of the pathology that are treated with these procedures.

ANATOMY
- Typical knee extension range is 0 degrees (full knee extension).
- Posterior capsular contracture can result from the imbalance between spastic or contracted hamstrings and knee extensor dysfunction (often associated with patella alta).
- Distal femoral anatomy is normal, although torsional deformity (excessive femoral anteversion) is commonly seen in neuromuscular conditions, especially cerebral palsy.

PATHOGENESIS
- The pathogenesis of knee flexion deformity and crouch gait in cerebral palsy will be described, as it is the most common condition to be treated with this technique. However, other causes of knee flexion deformity and persistent crouch could be treated similarly.
- Preterm, perinatal, or infantile brain injury leads to static encephalopathy.
- This neurologic disorder causes hypertonia (commonly spasticity), impaired motor control, and weakness.
- Typical muscle growth results from the tension produced by normal bone growth and age-appropriate, typical gross and fine motor activities.
- Musculotendinous growth in children with cerebral palsy is delayed because spastic muscle does not grow normally in response to stretch and delays in attainment of typical functional activities.
- Bone growth and joint development are also adversely affected by a lack of normal functional activities, as well as spasticity and musculotendinous contracture.

NATURAL HISTORY
- Crouch gait is not uncommon at 5 to 7 years of age. At these ages, the primary causes are spasticity, weakness, and impaired balance mechanisms.
- If crouch persists during later childhood, musculotendinous contractures of the two-joint muscles (psoas, hamstrings, rectus femoris, and gastrocnemius) develop. Persistent alignment in a crouch position leads to excessive elongation of the one-joint muscles (gluteus maximus, quadriceps, and soleus), which are primarily responsible for normal upright posture.\(^1\)
- The soleus, in particular, is responsible for restraining the forward movement of the tibia over the plantigrade foot (also known as the plantarflexion–knee extension couple).\(^3\) As a result, the ground reaction force vector typically falls near the knee joint in midstance, minimizing the demand on the quadriceps to maintain knee extension.
- If weak or elongated, the ankle plantarflexors are no longer able to restrain the forward movement of the tibia over the plantigrade foot (loss of the normal plantarflexion–knee extension couple).
- Further growth leads to loss of knee joint mobility and the development of posterior capsular contracture.
- For some patients in adolescence, pain from stress fractures or from excessive stress in the patellofemoral joint itself can lead to a precipitous worsening of crouch.
- Knee pain, decreased ambulatory function, or the loss of walking ability in adulthood in individuals with cerebral palsy is common.\(^3\)

PATIENT HISTORY AND PHYSICAL FINDINGS
- Physical examination methods include the following:
  - Knee range of motion: Loss of extension indicates a posterior capsular contracture; loss of flexion could be due to quadriceps contracture and especially rectus femoris spasticity or contracture if the knee is flexed in the prone position. Normal upright walking requires full knee extension range of motion.
  - The examiner should palpate the inferior pole of the patella and tibial tubercle. This distance is typically equal to patellar length. The patella is pushed medial to lateral to detect patellar instability. Patella alta, which can be a cause of knee pain or can contribute to knee extensor dysfunction, is suspected if:
    - The distance from the inferior pole of the patella to the tibial tubercle exceeds patellar height.
    - The patella is unstable medial to lateral.
    - The patellar tendon (as opposed to the patella) lies in the patellofemoral groove.
    - With the knees in extension, the superior pole of the patella is typically one fingerbreadth proximal to the adductor tubercle.
  - Knee extension lag test: Normal extension lag is 0 degrees. Terminal knee extension strength is required to control knee flexion during loading response.
  - Hamstring contracture: Normal popliteal angle can be as much as 30 degrees during preadolescence. It is commonly
greater in boys than in girls. For differential diagnosis purposes, it is important to identify all potential contributors to crouch gait.

- If resistance is felt as the popliteal angle is being assessed, hamstring spasticity is identified. If the knee is flexed with the patient prone and the hip extended, spasticity of the rectus femoris is identified.
- Spasticity is one of the primary causes of the series of events that ultimately leads to crouch. If severe enough, direct spasticity treatment may be necessary.
- A complete examination of the patient should also include evaluation of associated abnormalities to identify all potential contributors to crouch gait, including hip flexion deformity, hamstring contracture, femoral anteversion, tibial torsion, foot deformity or instability, balance disorder, and visual or sensory disturbances.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- A plain lateral radiograph of the knee in maximum extension should be obtained to assess for fixed knee flexion contracture and patella alta (FIG 1).
- If the knee is held in maximum extension, the femoral–tibial angle on the lateral radiograph represents the degree of true knee flexion deformity.
- The knee is extended maximally with a bolster just below the patella to assess the true degree of patella alta. Patella alta can be documented using the Insall ratio or the Koshino index.²
- Inferior-pole sleeve avulsion injuries of the patella are common in children with spastic cerebral palsy and can be identified on the lateral radiograph. The development of a stress fracture is typically painful and can lead to the rapid progression of crouch over a short period.
- Computerized gait analysis provides much-needed insight to create a problem list to guide treatment decision making by identifying the numerous other contributors to crouch listed above.

**DIFFERENTIAL DIAGNOSIS**

- Knee extensor lag with or without patella alta
- Hamstring spasticity or contracture
- Hip flexor spasticity or contracture
- Femoral anteversion
- Tibial torsion (typically external)
- Ankle plantarflexor insufficiency
- Foot deformity
- Excessive midfoot instability
- Soleus weakness: primary versus iatrogenic from prior Achilles tendon lengthening

**NONOPERATIVE MANAGEMENT**

**Preoperative Planning**

- The lateral radiograph of the knee in maximum extension should be reviewed for the degree of knee contracture, patellar height, presence of a stress fracture at the inferior pole of the patella, and the status of skeletal maturation (see Fig 1).
- Gait analysis data should be reviewed to assess for knee extension lag, degree of crouch, presence of hip flexion contracture, spasticity or contracture of the rectus femoris, and hamstrings length and for the presence of tibial torsion, femoral anteversion, and foot deformity.
- Examination under anesthesia for femoral anteversion and coronal-plane malalignment of the knee should be accomplished before positioning.
- Other deformities can be addressed concurrently under the same anesthetic.

**Positioning**

- If severe femoral anteversion is present, a proximal femoral osteotomy may be required in addition to the distal osteotomy, as it is difficult to correct more than 25 to 30 degrees of malrotation distally.
- Tibial torsion and foot deformity should also be addressed first. While these can be done supine, I prefer prone positioning.
Prone positioning is preferred as it allows accurate examination and correction of rotational profile consistent with the physical examination methods used in the clinic.

- The extension osteotomy and patellar advancement are performed supine with the leg draped free (FIG 2).

Approach
- The extension osteotomy of the distal femur is performed via a lateral distal femoral incision.
- The patellar advancement is performed through a direct anterior incision centered over the tibial tubercle.

DISTAL FEMORAL EXTENSION OSTEOTOMY

- The procedure is performed under tourniquet control.
- Through the lateral distal femoral incision, the fascia is opened and the vastus lateralis is reflected from its posterior origin and elevated to expose the distal femur subperiosteally.
- Circumferential subperiosteal retractors are placed.
